Then take samples from the same source. Add a known delay to one channel until you have reproduced the distinctive pattern you had observed when testing the felay between the points that have the unknown phase difference.

With a few elaborations, that`s how a phase monitor works.

Best regards, Richard Harrison, KB5WZI

> inductors at self-resonance to inductors operating away from
> self-resonance.

Quoting from the previously referenced paper: ".. is an approximation ...
appropriate for quarterwave resonance and is valid for helices with
(5*N*D^2)/lamda < 1. N is the turns/inch, D is the diameter of the
coil, and lamda is the self-resonant frequency. That calculation
for my 75m bugcatcher coil is ~0.4 so it meets the criteria.

The VF calculation of 0.175 is therefore valid. There is no valid
reason to suspect that the VF wouldn't hold approximately down to
4 MHz and below. There is no warning of such abrupt shifts in the
VF anywhere in the article. And Dr. Corum's VF equation is close
enough to my rough earlier estimate of 0.15 to be acceptable.

> you'll see time delay is essentially flat except near the 16MHz
> self-resonant frequency and a higher-frequency resonance at 26 MHz.

But cos(kz)*cos(wt) is what is being measured. That signal has zero
phase shift from tip to tip in a 1/2WL thin-wire dipole. It cannot
be used to measure phase shift because it is incapable of a phase
shift through 180 degrees of wire or 180 degrees of coil. It only
changes phase every 180 degrees of a wire or coil.

What is happening in the above measurement is that when the coil
is more than 1/2WL, the phase of the standing wave current suddenly
reverses from close to zero to close to 180 degrees. This is all
explained in Kraus', "Antennas for All Applications", 3rd edition,
Figure 14-4 and is perfectly understandable. The phase of the standing
wave current changes from zero to 180 degrees every 1/2WL. I've seen
exactly the same thing in my experiments just as Kraus predicts and
it supports my side of the argument.

The standing wave current, which has unchanging phase, cannot be
used to determine the phase shift in a wire or coil. A
signal with a cos(kz)*cos(wt) equation doesn't change phase
with variations in 'z'. How can it possibly be used to detect
phase changes in the 'z' dimension?

Many analog scopes aren't capable of producing a meaningful Lissajous figure at HF because of the limited bandwidth of the horizontal channel. Significant phase delays occur at frequencies well below the nominal cutoff frequency, which is often much lower than the vertical channel. Before believing in the validity of any figure, you should look at the figure you get when you apply the signal to both axes at the same time. If it deviates significantly from a single diagonal line, you won't be able to trust other patterns.

It would be a simple matter for a digital scope to present a good Lissajous figure, since the bandwidth is determined solely by the input samplers rather than a series of amplifiers and the CRT deflection structure as in an analog scope. I haven't looked closely at digital scopes lately, but I'd be surprised if most don't have the capability of making a good Lissajous figure at HF. It would be simply a matter of internal firmware programming.

Of course, a dedicated phase monitor would be designed for good phase and amplitude match between channels at the frequencies it's specified to be used at.

Actually, I just wanted to calculate the values for my own personal edification. You'll have to do the arithmetic yourself, Cecil, and then it won't mean much, because, as far as I know, no one has ever done any experimental work to see if these equations have any meaning. If a coil can slow down an electromagnetic wave as much as these equations say it can, though, it qualifies as a very interesting device.

OK, here is number 2. Hmmm wait... couldn't we use a different
ranking...

I retired from the industry and I worked for the original developer of
"Silastic RTV (TM)". My address if Midland MI if any one needs another
hint.

Yes there is an weak acid released from the regular RTVs and it
depends on the moisture in the air to aid in curing.

Is it, or will it be a problem? That is a Yes and no, or it all
depends answer.
I use plain old fashion "bathtub calk" on my antenna connections and
connectors *outside or outdoors*

The acid is not normally a problem *except* where the item is either
potted, or enclosed in a container. I would not use it on PC boards
where the foil is thin.

Outdoors I just "gob it on".

As to real corrosion:
Some years back we purchased a bunch of remote sensors that were
potted in metal boxes for use in harsh environments. They worked very
well... for about a year. One failed and who ever removed it brought
it into the shop. I decided to perform an autopsy on it. I cut the
seal, pried off the cover, and dug out the circuit board, or rather
what was left of it. The copper traces were mainly a green powder
with bigger chunks of powder around the solder joints where the wires
hung loosely.

The manufacturer of the sensors had used the wrong potting compound.
Had they used the neutral stuff (really stinks) they would have been
fine. They replace them all, they were expensive, and we had a bunch.

There are two main producers of RTVs and the formulations are pretty
much standard. If you analyzed a tube of the stuff I doubt you could
tell which manufacturer produced it. However they have slightly
different formulations aimed at the specific use. What every you
purchase under what ever brand name most likely comes from one of
these two producers unless it says Made in China.

That outgasing from a think layer will go on for many days which would
make it impractical to use in this case.

>not realising they were trapping the acetic acid vapour inside. The same
>can happen in balun boxes and the like.
>
In this case it would also depend on how much RTV, or how thick the
layer of RTV. As I said, the outgasing will go on for quite some time
and the thicker the longer it outgases. I'd not use the acid smelling
version from either producer on PC boards.

>It would be interesting to know if there have been *any* cases that
>didn't also involve some kind of closed situation, or possibly a layer
>that was too thick to let the vapour diffuse out.

A thin layer should cause no problem if it is given time to outgas,
but a thick layer will most likely eventually ruin the PC board.

Tom,

Here's another way to think about it.

If an inductor by itself delayed phase as much as Cecil claims, we could build a phase or time delay system with only a large inductor. As it is, we must always use a network of capacitors and inductors to obtain phase delays or a transmission line of any substantial delay.

To construct a delay line, either a small parallel wire line is used or a spiral around a metal core. The metal core acts like a shorted turn and reduces flux coupling, and adds distributed capacitance to ground.

There is another explanation.

A lumped circuit has only one resonance. A transmission line has an infinite number. It certainly isn't necessary to impose a strict test of this. Finding second, third, and fourth harmonics for an inductor, in situ, would certainly be compelling evidence of transmission line behavior. Otherwise, any delay obtained through pencil whipping the various formulas (and Reggie's equations veer far from the references offered) is strictly what occurs AT RESONANCE, and any interpolation of that delay to other frequencies is a presumption not yet proven.

This is certainly true for poor scopes. If we are limited to HF, then
those with bandwidths above 100MHz might squeak by. However, there
are alternatives that were part and parcel to many older scopes: you
simply drive the plates directly like they did in the old days (1930s)
before the plates were driven by dedicated amplifier chains.

I have calibrated such old (very old) scopes that operated well out
into the 100s of MHz, but were often accompanied by a necessary
accessory, a microscope.

Hi,

I followed the links provided by some of you for correction factor calculation and managed to find a folded dipole design that accounts for elements through the boom that are connected to it electrically.

I found from another link a construction method for the folded radiator and balun match. The design shows the shield of coax feedline and balun being connected to the boom but the elements in that second design are isolated from the boom.

Q: Can I still ground the coax to the boom if the elements are also attached to the boom ?

Thanks

Regards

David

Either you missed my point, or we differ on what constitutes a "poor"
scope. The Tektronix 465, for example, is a 100 MHz scope. Although it's
very long in the tooth now, it's not a "poor" scope by most measures.
But the specifications for X-Y display are as follows:

------

5 mV/div to 5 V/div, accurate ï¿½ 4%. Bandwidth is dc to at least 4 MHz.
Phase difference between amplifiers is 3ï¿½ or less from dc to 50 kHz.

This wouldn't produce a meaningful Lissajous figure at HF.

This is a misapplication of transmission line formulas. The "C" in those formulas is the shunt capacitance per unit length between the conductors, not a series or longitudinal capacitance as used here. In order to use the transmission line formulas, you have to have a second conductor and determine the C per unit length between the two conductors. Otherwise, you (or Cecil) have to come up with some other equations. Some of the more picky of us readers will of course then ask for the source and/or derivation of those other equations.

Roy Lewallen, W7EL

There are references for it in the Dr. Corum IEEE paper.
Kandoian and Sichak, "Wide Frequency Range Tuned Helical
Antennas and Circuits," Electrical Communications, Vol 30,
1953, pp. 294-299. It was published while I was in high
school.

> If a coil can slow down an electromagnetic wave as much as these
> equations say it can, though, it qualifies as a very interesting device.

I studied such 50 years ago at Texas A&M from papers
such as the above. The parameters for a transmission line
or a coil are the same just with different values.

We can build a time delay system with only a large inductor.
That's what large inductors do. How does a large inductor
cause a large arc on a Smith Chart without shifting the phase
of the signal?

One cannot use the presuppositions of the lumped-circuit
model to prove that there is no time delay through a
coil. The lumped-circuit presupposes zero time delay
through a coil with propagation times exceeding the
speed of light.

Using the same coil stock as W8JI's 100uH coil, I just set up
a 50 uH coil on a mag mount sitting on my metal desk. Its
first solid resonance was 9 MHz (1/4WL), its second solid
resonance was 27 MHz (3/4WL), and its third solid resonance
was 45 MHz (5/4WL). In addition to those, there other soft
spots and double dips along the frequency line.

W8JI reported something happening at 24 MHz as well as self-
resonance at 16 MHz. He was apparently not testing it over
a ground plane like an automobile body. That automobile
ground plane drops the VF much lower than an isolated
coil's VF.

One certainly has to be careful. But Dr. Corum's formulas
matched my measurements closer than I expected.

One thing is for sure. One cannot use the presuppositions
of the lumped-circuit model to prove the validity of the
lumped-circuit model and that is what has happened so
far. One also cannot use a signal with unchanging phase
to measure the phase shift through a wire or coil.

Yes, it's been known for over a century that the phase of the current through an inductor lags the voltage across it, resulting in retardation of the current relative to the voltage. And the time constant you refer to is of course the time constant of the rise or decay of the current through an inductor to which a voltage step is applied.

I don't see the connection between these and the contention that the current into and out of an inductor are unequal. If there is one, perhaps you can explain it. My texts all show a single equation relating the voltage across an inductor to the current through it, as follows:

v = L * di/dt

This holds at all frequencies, i.e., all rates of change of current, and it's from this that the above mentioned characteristics follow. If the currents at the two inductor terminals are to be different, we'll need two equations, one for the input current and one for the output current. That is, v = f1(di1/dt) and v = f2(di2/dt), where f1 and f2 are different functions. Have you come across such a set of equations in your searches through your textbooks, or are the authors unaware of Cecil's theories?

US Navy, fighting corrosion since the Year 1, banned the use of most kinds of silicone sealers and "RTV" in weatherproofing of topside connectors about 20 years ago. It was seen as a boon when it came out and was used extensively, both in the non-hardening varieties as a filler and in the rubberizing kinds as an outer coating. Too bad that many types proved to cause sufficient corrosion to be more of a problem than a solution! Since then, the Navy has gone through Skotchkote and into Pro-seal and other chemicals whose names I forget. Mechanically, we're getting into some exotic Gel-in-the-Middle connector sleeves. (We not only fight on the sea -- we have to fight the sea, itself.)

I will see what I can dig out of the files to document this. Keep your fingers crossed, as the archives shrink a little every year and the data might be gone.

Roy Lewallen wrote:
> Have you come across such a set of equations in
> your searches through your textbooks, or are the authors unaware of
> Cecil's theories?

I can't take credit for them, Roy, since I studied them at Texas A&M in the 50's. Much of it appears in Ramo and Whinnery's "Fields and Waves" and Johnson's "Transmission Lines and Networks". They are just the rules of the distributed network model of which the lumped-circuit model is a subset. In any situation where the lumped-circuit model yields different results than the distributed-network model, the lumped-circuit model is wrong.

The lumped-circuit model presupposes the conclusions that some people are presenting as fact. Obviously, the lumped-circuit cannot be presented as evidence of proof of its presuppositions. But it appears that is exactly what has happened. The lumped-circuit model presupposes faster than light propagation of signals. That alone should be enough to raise a red flag. Can someone prove faster than light speed by quoting the presuppositions of the lumped-circuit model?

Quoting Dr. Corum again: "Lumped circuit theory isn't absolute truth, it's only an analytical theory ... The engineer must either use Maxwell's equations or distributed elements to model reality."

My 75m bugcatcher meets his criteria for situations where his VF equations work. It yields a VF of 0.0175 for the bugcatcher coil. That VF works just like the 0.66 VF works for RG-213. On a coil physically like the W8JI test coil but with 50 uH inductance, I see coil resonances at 9 MHz, 27 MHz, and 45 MHz, just as if it were 1/4WL of transmission line. It appears that the calculated VF works over a wide frequency range.

To prove the presuppositions of the lumped-circuit model, a standing wave current is used to measure phase. We already know the phase of a standing wave current is unchanging all along a 1/2WL dipole, per Kraus, yet some people

keep using standing wave current with its unchanging
phase to try to measure phase shift as if it were a
valid thing to do. One cannot measure a phase shift
in 45 degrees of dipole using standing wave current.
Why is it surprising that one cannot measure a
phase shift in 45 degrees of coil? There's no
current phase shift from the top of the coil
to the tip of the antenna either.

Hi Roy,

Well, it (the misapplication) certainly is that. That no two numbers
agree to the same problem misses more compelling evidence that hardly
demands strict accuracy in results obtained from any formula.

In short, no "other" equations are going to prove what cannot be
generally demonstrated.

Barring startling results demonstrating how either of the two coils
offered here in evidence reveal multiple resonances, that is enough to
kill the thread without needing tedious computations.ï¿½

Another is the howler that this is all based upon the "coil's
characteristics," and Cecileo proved the Sun orbits the moon by
employing the bed of his truck in the exact solution.ï¿½ This is called
new-age math with an harmonic convergence. It was convenient of all
his reference sources to include this truck factor as a hidden
variable - accessible to only those who know the secret handshake.

Just kidding, of course.

In fact, the authors tread very lightly in the context of a ground,
mentioning it only once as a necessity for
"characterizing the impedance of a structure
at a pair of terminals" [your point]

When the speculation is that the coil presents a 1:1 replacement for
the delay of the "missing" segment of the resonant antenna, then this
premise stumbles at the starting blocks. If I shorten the whip, then
the shorthand of:
>On Tue, 14 Mar 2006 21:45:06 GMT, Cecil Moore <mycall@arrl.net> wrote:
>>The velocity factor can also be measured from the self-
>>resonant frequency at 1/4WL. VF = 0.25(1/f)
offers this promise:

Make a smaller inductance (reducing turns will do)
to present a higher self-resonant frequency.

VF will fall.

From this, the delay climbs
to replace the shortened whip's missing angular contribution.

The reductio-ad-absurdum is that we repeat the trimming of the whip
until the inductance disappears.ï¿½ Ironically this leaves us with a
very short mast that now resonates! If we closed our eyes really,
really hard, and wished for a coil with a very high self resonance, it
could replace the mast too.

I see new marketing possibilities for 80 and 160 Meters.

ï¿½ ï¿½ ï¿½ Let's see, without any deep computations I count three thread
busters here. Offering the same proviso of probable computation
errors committed here, I would point out that only one thread buster
need survive to present the obvious fate to this theory.

Nor do I. Tom was not making a case for inequality of current in and out of a coil either. He was just making an inaccurate statement.

Cecil has a good case. Straight wire and coiled wire have the same properties, only more or less of them. When they are in the path of a traveling wave and a reflection of that wave comes back from the opposite direction, they respond similarly. An interference pattern exists on the coil as it does on straight wire if the distance is comparable to a wavelength. Superpositon makes both volts and amps vary along the route.

So, indeed the current at one end of a coil in that situation can be different at from that at the other end, the same as it would along a wire.

Distributed network theory is newer than lumped network theory but both have been around plenty long enough to be well established. I don`t think Cecil is breaking any new ground.

Which distance do you mean -- the length of the coil or the length of the wire?

Superpositon makes both volts and amps vary
> along the route.
>
> So, indeed the current at one end of a coil in that situation can be
> different at from that at the other end, the same as it would along a
> wire.

Yes, indeed. As I explained in several earlier postings, if you begin with a coil and slowly stretch it out, the current distribution will go from something resembling that of a lumped inductor (equal currents in and out) to that of a straight wire (sinusoidal distribution). So "a coil" can have any current distribution along that continuum, allowing us to "prove" just about anything we wish as long as we don't say what kind of coil we're talking about. In between the extremes, a third distribution can occur, as King described in his book: when the coil length is much less than a wavelength but the turns are loosely coupled, you get a current that's highest in the middle and lower at both ends. The disagreement regards the currents in what would qualify as a lumped inductor -- one with very good coupling between turns, coil length very short in terms of wavelength, and no significant coupling to other conductors, but regardless of the length of wire it's made of. For that case, it's been theoretically and demonstratively shown to be equal at both ends.

> Distributed network theory is newer than lumped network theory but both
> have been around plenty long enough to be well established. I don`t
> think Cecil is breaking any new ground.

His conclusions are sure new and different, and unlike established
theory, his theories don't seem to be subject to equations which
describe them quantitatively.

> for Delta/a > 6 to be acceptable.

Yes, and now I am wondering where I got this value of 6 instead of 8...

However when delta/a (len/radius) < 6 a warning is generated, when
delta/a < 2 an error is generated. When using more thick wires, you can
add the EK card. With this more high delte/a values are possible.
(warning if delta/a < 2, error if delta/a < 0.5).

>but a thick layer will most likely eventually ruin the PC board.

Agreed; but that isn't really the fault of the silicone material. It's
more like "misuse".

But why do we use silicone for coax/antenna sealing anyway? Anything for
which you might use silicone could probably be done a lot better using
hot-melt glue.

Ordinary hot-melt glue (amorphous polypropylene) has good RF properties,
is non-corrosive, is very sticky, seals very well to metals and
plastics, is flexible, has no problems about being used in thick layers,
sets in minutes rather than hours, has at least as good weathering
properties as silicone, can be removed by cutting, peeling or melting,
and is very economical.

You can often use it in the backyard without electrical power, because a
typical glue gun gives up to 5 minutes working time after having been
unplugged.

There's more information in the archives of this group, thanks to Barry Ornitz, WA4VZQ.

Neumann didn't prove that the current through a coil is uniform.
He *assumed* it to be true as a simplification, so he could factor
out the current term from under the integral sign in one of Maxwell's
equations. Now Neumann's mathematical shortcut is being reported
here as a fact of physics. That's how well established it is.

Roy Lewallen wrote:
> For that case, it's been theoretically and demonstratively shown to be
> equal at both ends.

Only one of the reported measurements showed the magnitudes of
the currents to be equal and that was a small toroidal coil
quite unlike a 75m bugcatcher coil. Wes's web page shows the
currents to be unequal at the ends of the coil. Figure 3 shows
1.03 amps at the bottom of the coil and 0.66 amps at the top
of the coil. That's not equal.

http://www.k6mhe.com/n7ws/Loaded%20antennas.htm

--

Here's an example from EZNEC where the currents are not
only unequal, but if one considers to standing wave current
to be flowing, more current is flowing into the bottom of
the coil than out the top. What does the lumped-circuit model
have to say about that? This technical question goes unanswered.

http://www.qsl.net/w5dxp/qrzgif35.gif

--

As for phase shift using standing wave current, consider the
following half of a dipole:

FP----------x----------y----------

'x' is at the 30 degree point and 'y' is at the 60 degree
point. What is the standing wave phase shift between point
'x' and point 'y'? We can see from Figure 14-4 in Kraus'
"Antennas for All Applications", 3rd edition, that the
measured phase shift would be zero between 'x' and 'y'.
So why is it a surprise that if the wire between 'x' and
'y' is replaced by a coil, the phase shift remains zero?
The measured phase shift in the wire and the coil are the
same. This technical question goes unanswered.

I think what we have here is Cecil has bought into the idea that radically different behavior on one or more self-resonant frequencies means we can apply an analogy of that behavior to all other frequencies.

Most of us probably want a theory that works all the time, and we probably think only one situation that proves the theory wrong is required to dismiss the theory as being incorrect.

What Cecil is asking us all to do is is agree to a theory that only works in special cases and ignore the times it does not.

False. Nobody has said anything about "all other frequencies".
The distributed network model covers a wider range of frequencies
than does the lumped-circuit model. At some frequency below self-
resonance in coils the lumped-circuit model fails. One must know
when to switch over to the distributed network model or one makes
mistakes of the kind that have been posted here. Dr. Corum suggests
switching over at a frequency 15% of the self-resonant frequency.
I would say that percentage is too high. 54+j100 is not the same
as 50+j0. It is not even close.

> Most of us probably want a theory that works all the time, and we
> probably think only one situation that proves the theory wrong is
> required to dismiss the theory as being incorrect.

The lumped-circuit model fails under conditions where the
distributed-network model continues to work. The lumped-
circuit model fails most of the time when standing waves
are present. The problem here is that some think the
lumped-circuit model works all the time but they are
mistaken.

> What Cecil is asking us all to do is is agree to a theory that only
> works in special cases and ignore the times it does not.

The lumped-circuit model is the special case, a subset of
the distributed network model. The lumped-circuit model assumes
that current flows faster than the speed of light. The distributed
network model makes no such false presuppositons. The lumped
circuit model is a simplified subset of the distributed network
model. If there is any disagreement between the two models, the
distributed network model wins every time.

Here is a graphic generated with the help of EZNEC. It shows
the same bottom-loaded antenna at its resonant frequency of

5.89 MHz, double that frequency, and triple that frequency.
The current magnitudes and phases are shown at various points
on the antennas. These values match my measurements.

http://www.qsl.net/w5dxp/3freq.gif

I have asked many technical questions that remain unanswered.
Please answer these technical questions about that graphic:

1. At 5.89 MHz, how could the phase of the current be almost
constant? Why is the phase shift halfway up the whip virtually
identical to the phase shift at the top and bottom of the coil?

2. At 5.89 MHz, the phase shift is essentially zero from feedpoint
to tip. How can no phase shift through the coil be important when
there is no phase shift through the whip?

2. At 11.78 MHz, how could 0.1729 amps be flowing into the
bottom of the coil while 2.014 amps flows out of the top of
the coil? How could there be a 180 degree phase shift through
the coil? Why is the phase halfway up the whip the same as
the phase at the top of the coil?

At the most basic level, Cecil does not understand what scientific theories are all about.

That was not a "shortcut" or approximation. It was a rigorous test for the limiting case where the coil has no other properties except pure inductance, so no electromagnetic radiation is taking place. In that limiting case, Maxwell's equations MUST join up with conventional circuit theory... and indeed they DO.

In that limiting case, the current at the two terminals of a pure inductance must be the same in both magnitude and phase. By "current" we mean the simple, straightforward movement of charge. If you count the electrons in and out at the two terminals, there can be no difference in either magnitude or phase because that would require electrons to be stored or lost from somewhere - which inductance cannot do. Kirchhoff's current law recognises the logic of this.

This is how inductance always works in every type of non-radiating circuit, both in theory and in real life.

When developing a new theory, it is normal, standard required practice to test it for simplified, limiting cases that we already understand. The new theory MUST work for all these test cases; it MUST connect seamlessly with everything we already know.

At his point, some heckler pipes up: "Ah, but what about Einstein?" Thank you, sir - the perfect example to prove my point! If Einstein's equations of relativity are tested for the limiting case where velocities are very low, they connect seamlessly into Newton's laws of motion. If they hadn't, Einstein would have thrown them out and gone back to think again.

Another point: antennas are the home territory of classical physics, where everything is consistent with everything else. Classical physics is plain physical reality, verified every day, a billion times over.

All of our validated knowledge joins together completely seamlessly - and that's how we test anything new. In the home territory of classical physics, reality is hard, sharp and clear. It allows no gaps and no excuses. "What don't fit, ain't true."

Trained scientists accept the discipline of that, and turn it into a useful tool. Engineers aren't always trained to think that way, but the best are of a mind to do it anyway. They're creating new ideas all the time, and the ones that "don't fit" or "don't make sense" are simply abandoned (sometimes they're abandoned before they even make it into fully conscious thought). One way or another, lots of ideas get thrown away; no big deal, it's just part of the process of *having* ideas.

So...

When Cecil's theory is tested for the simple limiting case of pure inductance, it MUST join up seamlessly with conventional circuit theory. If it requires anything that "don't fit", such as a phase shift in current through a pure inductance, or special kinds of "current" that are different from the simple, straightforward movement of charge (electrons), then the theory fails.

OK. I'm not sure what you are trying to say. It sounds like we all know and agree a reasonable physial size lumped inductor with good flux coupling between ends and stray C to the outside world that is small compared to termination impedance works like a lumped inductor below self-resonance of the inductor. There is only a tiny transmission line effect and that effect has more to do with spatial size than conductor length.

So...

What are you trying to say? Can you give an example in you own words explaining what you are trying to say and why it is meaningful or useful to others?

Surely you can put it all into a few words.

Although Bob isn't asking about sealing connectors, this thread has
drifted that way.

If this is indeed his need, then I offer my method. I use
Plymouth-Bishop No. 122 rubber tape followed by an overwrap of a good
quality vinyl tape.

http://www.plymouthbishop.com/

If memory serves, I bought the 122 at Home Depot, although their web
site doesn't show that they carry it anymore. An electrical supply
house would likely be a source.

Not sure if "EK" will help much here since the "wire" diameter is >
lambda/100. Seems to be a borderline case for a wire grid model. It is
like building a 20m dipole from 10" diameter pipe.

Also noticed the pole touches the ground, which is not allowed in NEC2.
Don't understand why it does not produce a warning. Usually when I connect
a wire to a non-perfect ground the ground grid turns purple (NEC-Win Pro),
and I get crazy results, but not in this case. Not that this is relevant in
this model.

I absolutely agree about the characteristics of an inductor presupposed
by the lumped-circuit model. But one cannot use the presuppositions
of the model to prove the model is valid for all cases. The dissagreement
here is one of degree. I would have stated the assertion above, it behaves
"... like a lumped inductor *far* below self-resonance of the inductor." Dr.
Corum sets the "far below" range at 15 degrees or 1/6 the self-resonant
frequency.I previously showed that 15 degrees of 450 ohm transmission
line will change a load of 50+j0 into a load of 54+j100 ohms. That may
be accurate enough for Dr. Corum to start using the lumped-circuit model,
but not for me. I would be more inclined to set the limit at 5 degrees.

> What are you trying to say? Can you give an example in you own words
> explaining what you are trying to say and why it is meaningful or
> useful to others?

What I am trying to say can best be illustrated by an example task that
I need to perform. I have a 180 foot dipole that I need to shorten so I
am going to install loading coils. I want the length of the loaded antenna
to be 90 feet. I'm pretty naive at this, so I am just going to build the
coil
out of the wire I remove from the antenna. My neighboring ham friend
says that will work just fine. And in the process of reducing the size of
my antenna, I want to learn something about antennas so I have borrowed
two toroidal current pickups to measure the current.

Note that at the frequency where the dipole is 1/2WL and resonant,
it is 180 feet long and 180 degrees long so the number of feet of
wire is also the number of degrees of antenna. Here is my 1/2WL
dipole with current pickup coils installed at points 'x' and 'y' and
FP is the feedpoint,the impedance of which is 60 ohms.

```
------------------------------FP-------x---------------y-------
```

Total length is 180 feet. The distance between 'x' and 'y' is 45 feet.
Since feet = degrees in this case, the number of degrees between
'x' and 'y' is known to be 45 degrees from antenna theory. Those
45 degrees are what I am going to attempt to replace with a coil.

So I adjust the feedpoint current to one amp at a reference phase angle of zero degrees and measure the current at 'x' and the current at 'y'. The current at 'x' is 0.92 amp at 0 deg. The current at 'y' is 0.38 amp at 0 deg. Already I am not understanding my measurements. The electrical length between 'x' and 'y' is obviously 45 deg. Why is there no phase shift at all in the measured current between 'x' and 'y' and the feedpoint current? But I want to complete this task so I will wait until later for an explanation to that apparent paradox.

I take the 45 feet of wire from each side of the dipole, wind it into two coils, and install them in each side. Now the 90 foot long dipole looks like this.

-------//////-------FP------x-//////-y------

I make some more measurements with the feedpoint current set to one amp at zero degrees. The resonant frequency of the dipole has changed from the earlier resonant frequency. I have to adjust the number of turns on the coil to return to the original frequency. I discover that the feedpoint impedance has dropped to 45 ohms. I measure the current at each end of the coil and at one end it is 1.1 amp at 0 deg and at the other end it is 0.6 amp at 0 deg

These are not the results predicted by my neighboring ham friend. I'm confused but here are the things I know for sure.

1. The resonant frequency changed when I installed the coil so the coil is not a perfect replacement for the wire.

2. The feedpoint impedance decreased from 60 ohms to 45 ohms. Since 45 ohms is closer to 50 ohms than is 60 ohms, I'm not too interested in knowing why..

3. The current at 'x' increased from 0.92 amp at 0 deg in the wire dipole to 1.1 amp at 0 deg in the loaded dipole. The phase didn't change.

4.The current at 'y' increased from 0.38 amps at 0 deg in the wire dipole to 0.6 amp at 0 deg in the loaded dipole. The phase didn't change.

5. No matter where I measure the current in either system, the phase always comes up zero degrees between any two points from tip to tip anywhere on either dipole no matter how far apart are the measurement points. My neighboring ham friend said the number of degrees in the coil had to be the number of degrees in the wire and indeed, both are measured to be zero degrees, but I wonder if that's really what he had in mind when he said the delay would be equal. Zero equals zero, but what does that mean for me?

The change in feedpoint impedance and the different current magnitudes don't much bother me but I am really bothered by those phase measurements. The dipole is 180 degrees long

and the current should be changing phase, at least on the wire
if not through the coil. I need some expert to explain how those
phase measurements on the wire are possible on both antennas.
I know my phase measurements are correct but why are they
always zero degrees? And since they are always zero degrees,
what information are they providing?

:-) :-) :-) :-) :-)

It just occurred to me that those two posts were a week apart (more or
less) and denote a phase change (the one cancels the other if they
were to vectorally combined).

Thus and forever more, this proves that newsgroups (when heavily fed
from a source of confusion, linearly loaded with nonsense, and
terminated with a embarrassing revelation) exhibit transmission line
properties and can transform a stupid idea (at the top) into a
brilliant one (at the bottom) - or versa vice.

In conformance to transmission line properties, this cycle of phase
reversals is repeated every
1 / [1 + tan (c ï¿½ Vf / posts)]ï¿½ Years

Sorry Bill,

Depends....

Yes, of course not. The clear and compelling lesson to be learned is that you CANNOT apply Kirchhoff's laws to networks that are large in relation to wavelength. This single caveat was drilled into me in sophomore EE.

Any variance in current measured, that is larger than errors that may be attributed to is measurement PROVES that the size in relation to wavelength necessarily invalidates Kirchhoff solutions. This single truth has been observed by me at the calibration bench.

As Roy noted, it demands another set of equations. In the Metrology field, that is what we were paid to use, or to derive. Suffice it to say that modeling programs replace the tedium of scribbling out that math, and just getting on with the next act.

> That was not a "shortcut" or approximation.

It really doesn't matter if it is or it isn't. I was quoting another pretty smart guy who seems to know the history of these models. He said Maxwell's equations matured first, then the distributed network model matured as a simplified subset of Maxwell's equations, then the lumped-circuit model matured as a subset of the distributed network model. But a chicken/egg argument is meaningless except for historical accuracy. We are in the present looking at those models.

> In that limiting case, the current at the two terminals of a pure
> inductance must be the same in both magnitude and phase.

There's that catch word, "pure". Pure inductances do not exist in the real world. They are a construct of the lumped-circuit model and are presupposed to have the characteristice that you mention. One cannot prove the validity of that model by quoting the presuppositions. A 75m bugcatcher coil is NOT a pure inductance.

> By "current" we
> mean the simple, straightforward movement of charge. If you count the
> electrons in and out at the two terminals, there can be no difference in
> either magnitude or phase because that would require electrons to be
> stored or lost from somewhere - which inductance cannot do. Kirchhoff's
> current law recognises the logic of this.

Standing wave current with its cos(kz)*cos(wt) equation is not constrained by those rules since the phase of the standing wave is everywhere zero deg for a 1/2WL thin-wire dipole.

> This is how inductance always works in every type of non-radiating
> circuit, both in theory and in real life.

A pure inductance cannot work that way in real life because it doesn't exist in real life. If the forward current is in phase with the reflected current at one end of the coil, the current will be a maximum (loop) at that point. If the forward current is 180 degrees out of phase with the reflected current at the other end of the coil, the current will be a minimum (node) at that point. Please take a look at:

http://www.qsl.net/w5dxp/3freq.gif

How does one explain the current reported by EZNEC at two times the resonant frequency?

> When developing a new theory, it is normal, standard required practice
> to test it for simplified, limiting cases that we already understand.
> The new theory MUST work for all these test cases; it MUST connect
> seamlessly with everything we already know.

The distributed network model predates my birth by decades and is not new. It is known to work in situations where the lumped-circuit model fails. It has never been known to fail in a situation where the lumped-circuit model works.

> At his point, some heckler pipes up: "Ah, but what about Einstein?"
> Thank you, sir - the perfect example to prove my point! If Einstein's
> equations of relativity are tested for the limiting case where
> velocities are very low, they connect seamlessly into Newton's laws of
> motion. If they hadn't, Einstein would have thrown them out and gone
> back to think again.

The distributed network model is to relativity as the lumped-circuit model is to Newtonian physics. Newtonian physics is a subset of relativity. The lumped-circuit model is a subset of the distributed-network model.

> When Cecil's theory is tested for the simple limiting case of pure
> inductance, it MUST join up seamlessly with conventional circuit theory.

It's not my theory and it does indeed join up seamlessly. It is the lumped-circuit model that does not join up seamlessly with Maxwell's equations. How could it since it assumes faster than light speed of current flow? The presuppositions of the lumped-circuit model even violate the theory of relativity.

> If it requires anything that "don't fit", such as a phase shift in
> current through a pure inductance, or special kinds of "current" that
> are different from the simple, straightforward movement of charge
> (electrons), then the theory fails.

It doesn't require anything of pure inductances since pure inductances don't exist in reality. It requires that real world inductances obey the laws of physics.

If one doesn't understand the implications of the equation for standing wave current, one needs to crack open that old dusty math book.

That does NOT say the coil replaces 60 degrees of wire in the antenna.
One who thinks such is mistaken. The phase shift in the coil is what it
is. It usually does NOT correspond to the phase shift of the wire it
replaces.
The point of that statement was that real world phase shift is never zero.
The one-way phase shift is known to be 90 degrees at the self-resonant
frequency.

news:44199e18_1@newsfeed.slurp.net...
> I've been following this mind-numbing discussion for days now and still
> don't have the answer to the original question:

Bill, I posted an example of me, as a naive ham, reducing the size of my
dipole from 180 feet to 90 feet by adding loading coils. Please follow
that experimental excursion to find out what the discussion is all about.

> Is the current the same at both ends of a mobile whip's loading coil?

The mobile antenna is a standing wave antenna. It has a forward current
and a reflected current, both traveling waves, flowing through it.

1. The forward current flowing through the coil is close to the same
magnitude at both ends of the coil.

2. The forward current phase shift through the coil is difficult to measure
but it is NOT zero. It is more in the neighborhood of tens of degrees.

3. The reflected current flowing back through the coil is close to the
same magnitude at both ends of the coil.

4. The reflected current phase shift is close to the same as the
forward current phase shift, i.e. tens of degrees..

5. The standing wave current, the only one measured so far, is the
phasor sum of the forward current phasor and the reflected current
phasor. The magnitude of the standing wave current depends upon
the relative phase between the forward current and reflected current.

To see some variations please visit: http://www.qsl.net/w5dxp/3freq.gif

When one realized that the standing wave current at the bottom of
the coil is 0.1 amp while the standing wave current at the top of
the coil is 2 amps, one comprehends why he must abandon the
concept that standing wave current flows.

From the equation for the standing wave current, cos(kz)*cos(wt),
one can be see that the standing wave current is not a normal current.
This is explained in terms of light waves in "Optics", by Hecht.

6. Since the forward current phasor and reflected current phasor are
rotating in opposite directions, the phase of the standing wave current
is fixed and close to zero degrees all up and down the antenna, from
feedpoint to tip top. Since the phase of the standing wave is unchanging,
it cannot be used to measure the phase delay through a coil. All of the
delay measurements, except the self-resonant frequency measurements,

have used standing waves which are incapable of phase transitions in the average loaded mobile antenna.

The phase of the standing-wave current is fixed close to zero degrees until the antenna gets electrically longer than 90 degrees. Then it shifts abruptly by 180 degrees and remains fixed at that new value for another 90 degrees. This is illustrated in Kraus', "Antennas for All Applications", 3rd edition, Figures 14-4 - 14.6.

Most hams have an awareness of what skin depth is all about
but I am stumbling over the fact that the formulae show it
as a 2 dimensional thing which raises a question to me.
Can one compensate for radiation purposes element width
for lack of the required skin depth and also what role
does skin depth play with homogenous or
non-homogenous capacitive (capacitor) fields.?
Both of these items contain inductance and resistance
but apparently volume which is three dimensional does not
play a role.
Can somebody explain this personal puzzle of mine or
point to a book that points to the lacking volume aspect ?
The above questions I suppose could come into play
if one thought about aluminised mylar for antenna use
which has about the thinnest conductor depth around.
TIA

Source record: 62982

Hello all,
I put up a linear-loaded dipole this past fall/Oct. The feedpoint
was at 55ft.,and the ends
which are 70ft. long were at 15ft. above the ground. I use a Heathkit
2060a manual tuner.
I was able to use 80ft. of 450ohm ladderline,to a 4/1 balun at the
window,and then HAD TO USE 50FEET of 213 coax to the tuner!! I know
that it did give me all of 160m,BUT I wanted
to have a shorter run of coax,also the coax was "reactive". If I moved
it or wiggled it the meters would jump all over the place !! Many
told me that I needed to experiment with the length of
ladderline;getting it to a certain amount of "wavelength". Well, we
had some good weather,and I really wanted to get rid of that long coax
in the house,so I cut my ladderline to
exactly 62.3 feet,then added the balun outside on the tower,and went
213 coax the rest of the way. IT'S WORKING FANTASTIC. Its only been a
couple of days now,but I can see that it tunes much better,has less
refelected power,it doesn't "snap" or "crack" in "dissagreement
with the lengths,......just more happier.
Thank you to all who shared their opinions and ideas
with me.

on to the
next problem, 73's, Paladinghh

Bill,

Did you read this? Actual measurements!!

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

As Richard Clark said, it all depends on the physical size and
constrution of the inductor and the antenna above the inductor. In a
reasonably well-constructed antenna the difference is small.

Anyone who says otherwise is just guessing.

Not much accuracy is needed to measure a constant phase of zero.
Anyone is invited to duplicate those phase measurements.

> When did you measure that? After we resolve the error in current, we
> can move on.

I rigged up a 6m dipole yesterday with current pickups driving equal
lengths of coax. Remember, we are not discussing the accuracy of
my magnitude measurements, only of my phase measurements.

After we resolve exactly who made the measurement error, we can
move on. My measurements agree with Figure 14-4 in Kraus'
"Antennas for All Applications", 3rd edition.

Question: would it be legal for me to scan that graphic and post it
on my web page if I give Kraus full credit?

Indeed, Ian. Just so.

It's amazing to me that this thread has gone on for so many postings. (And here I am contributing to it! ;-) But I go back to the very first posting in the thread, where Reg said it all. Well, maybe not QUITE all, but close. I'd invite folk to go back and look at that posting. I believe Reg noted that a real physical (single-layer solenoid) coil has: inductance, capacitance (with a radial electric field), wire resistance and radiation resistance. One additional item I'd like to note is turn-to-turn capacitance; Reg may have been thinking of that one too, but I didn't get it explicitly from his posting.

Measuring currents doesn't present too much of a challenge if one is careful about it, but measuring voltage is an entirely different matter, since it's in the presence of a time-varying magnetic field if there is any current in the coil. But it is possible to measure the electric field and the magnetic field if one wishes.

I have not been following this thread very closely, because I really do NOT expect "the answer" to be any different than what, as Reg noted in that initial posting, is predicted by an ACCURATE model. People who designed travelling wave tubes understood very well the properties of a helix of wire with respect to propagating a wave. The software I've been using for years now to predict single-layer solenoid coil behaviour takes into account all the interesting effects, and will predict quite accurately the first parallel resonance and the first series resonance, the Q, the inductance, and fundamental transmission line characteristics below resonance. I have other resources that let me predict the change in behaviour when a coil is inside a shield. I've never been surprised by any of the results: taken to correct limits, they all join up, as Ian notes, with conventional circuit theory. In fact, even the complex models match conventional circuit theory, just with more elements in the model.

I do note that one must be careful about exactly what conventional circuit theory actually says. For example, many people seem to think that Kirchoff's Voltage Law is something like, "voltages around a loop add up to zero." That is an abbreviated statement of the law, and is in general not correct.

Cheers,
Tom

No, it isn't, provided it's a solenoidal coil of reasonable length. I don't think anyone disagrees with this. The disagreements are to why, and what would happen to the current if the coil were made very short.

Cecil,

One more time.

In a standing wave antenna problem, such as the one you describe, there is no remaining phase information. Any specific phase characteristics of the traveling waves died out when the startup transients died out.

Phase is gone. Kaput. Vanished. Cannot be recovered. Never to be seen again.

The only "phase" remaining is the cos (kz) term, which is really an amplitude description, not a phase. The so-called "phase reversal" in longer antennas is not really about phase either. It is merely a representation of the periodic sign reversal seen in a cosine function. (This is one more definition of phase to add to the confusion.)

Of course, all of this depends on an ideal system with no losses, etc. The real world is not ideal, but your posed problem does not appear to contain any of those nasty realities. You have undoubtedly seen small phase offsets reported in EZNEC for this sort of antenna. Those phase offsets represent the impact of real-world effects, such as radiation and ground effects.

The applicability of linear superposition and the assumption of steady-state conditions means that the resulting standing wave contains ALL of the possible information about the system in steady-state mode. Yes, you can divide the problem back into two traveling waves, in the manner that Kraus, Balanis, and the entire world understand. But you won't gain any new information by doing so, because any unique traveling wave information is permanently lost.

73,
Gene
W4SZ

I need to add that the current can be different at both ends even if the coil is quite short in terms of wavelength. All that's required is capacitive coupling that's different from the two ends of the coil, or coupling to a radiating wire. Both are typically the case with an antenna loading coil. Another thing which can cause unequal currents is poor coupling among turns, which can occur in long coils or ones with wide turn spacing. But when the inductor length is short in terms of wavelength, the current imbalance can be explained with simple lumped element models. No distributed or transmission line theory, let alone Cecil's exotic variations, is necessary.

The measurement looks good to me. The phase is exactly what EZNEC
predicts -- constant along the wire. The ratio in magnitudes we'd expect
depends on the positions along the wire, not just the spacing.

The phase shift measurements are being made using a signal with
unchanging phase and thus incapable of providing a phase shift.

The disagreement is what would valid phase measurements actually
look like if a signal capable of changing phase was used to make the
phase measurements.

Hi Frank/Arie

Not really knowing what I was doing <grin> I tried EK and got the same bad average gain figure.. I also removed most of the lower part of the mast since its effect will be fairly minimal. No help there either.

Tnxs for your comments gents. There is still the two questions though;

- Does one bother to model in a "curved" wire for copper pipe joiners? I note Mr Cebik didnt mention it when he was talking about J poles on 2m.

- Is the diameter of the source wire important?

Thinking now about reducing the copper pipe diameter simply so I can model it properly. Then again its a pretty broad design and tuning would be easy...

Cheers Bob VK2YQA

For capacitors, charge does not reside "inside" the conductor, it is
between the plates (there's volume for you, A ï¿½ d).

For inductors, charge is found in the core (there's volume for you, 2
ï¿½ Pi ï¿½ r ï¿½ l).

For current, flow is forced to the surface due to repulsion of charge.

2884. Capacitance-of-a-wire conundrum

Just a little something to think about...

If I have a wire, radius r, nominally infinitely long, in free-space, does it have non-zero capacitance per unit length?

A sphere in freespace has capacitance directly proportional to its radius: C = 4*pi*epsion.zero*radius. So the earth, in something approximating freespace, has a bit over 40uF of capacitance. But what about a wire?

A coaxial capacitor (the capacitance between conductors of a coaxial cable, for example) with vacuum (or essentially with air) dielectric and inner conductor radius a and outer conductor inner radius b, has capacitance C per unit length L given by

C/L = 2*pi*epsion.zero/(ln(b/a))

As b goes to infinity (the wire in freespace case), C/L goes to zero.

So if I have a thin wire, 15 meters long, out in freespace, and a 10MHz (30 meter wavelength) EM wave comes along and passes by that wire, what happens in the wire?

Cheers,
Tom

What was the indicator? What was the coupling device?

On six meters, it would take a darned small probe and indicator to not greatly perturb the system.

If I was going to test something like this, I'd use a small indicator hanging from the antenna and do it on a low frequency.

So, tell us about the probe and indicator.

> as a 2 dimensional thing which raises a question to me.

Skin depth is a scalar quantity, not two dimensional. Perhaps you're referring to the fact that concentration of the current in a thin layer affects both the resistance and inductance of a conductor?

> Can one compensate for radiation purposes element width
> for lack of the required skin depth

I've never seen an application that requires a particular skin depth. Can you give an example?

and also what role
> does skin depth play with homogenous or
> non-homogenous capacitive (capacitor) fields.?

Skin depth is a property of conductors, not fields -- although of course it comes about because of interaction of fields with the conductors. If a capacitor is made from conductors, those conductors will exhibit skin effect like any others.

> Both of these items contain inductance and resistance
> but apparently volume which is three dimensional does not
> play a role.

Skin effect causes current to be concentrated near the surface of a conductor. Its density exponentially decays as you go deeper. Consequently, the fraction of the total current flowing below a few skin depths is insignificant, so the depth and makeup of the conductor below that depth makes no real difference to the resistivity of the material. That's why a hollow tube conducts just as well as a solid wire at radio frequencies.

> Can somebody explain this personal puzzle of mine or
> point to a book that points to the lacking volume aspect ?
> The above questions I suppose could come into play
> if one thought about aluminised mylar for antenna use
> which has about the thinnest conductor depth around.

I hope the brief description above explains why volume isn't important -- it's just that at RF there's no current in most of the volume of a wire or plate, so that volume which carries no current can be ignored.

As for your metalized Mylar, the first thing to do is to determine whether the aluminum is at least several skin depths thick. If it is, then any greater thickness makes no difference, and you can treat it as though that's all the thicker it is. If it's one skin depth or thinner, you can ignore skin effect and treat it as though the current is evenly distributed throughout the thickness. If it's in between those limits, the R and internal L can be calculated, but it involves Bessel functions. An estimate is usually adequate in those situations.

There's a great deal of information about skin effect on the web, although like most topics found there, you should read with caution. The subject is covered thoroughly in virtually every text involving electromagnetics, and most texts on transmission lines. I'd expect to find it covered in the ARRL Handbook as well.

I should add one final note. Due to a fortunate quirk of mathematics, the resistivity of an infinitely thick material at RF is the same as that of a material which is exactly one skin depth thick in which current is uniformly flowing. That is, if we know the skin depth we can easily calculate the RF resistivity by calculating the DC resistivity of a one skin depth thick layer of the material. It's important to realize that's not really how the current is distributed, but the method gives the correct answer. For this method to work with reasonable accuracy, the material has to be thick enough for the current to follow the exponentially dropping density characteristic down to a depth where it's insignificant. This is on the order of 3 - 5 skin depths, depending on the accuracy you require.

Source record: 62997

I'm not sure I understand 'zactly what the question is here...but perhaps if you step back a bit from the formulas, it will become clearer.

"Skin depth" is just talking about the fact that at high frequencies, current tends to flow only in the outer layer of a conductor. The effective thickness of that layer is the skin depth. If you have a conductor that's several skin depths thick (at the frequency of interest), the inside of that conductor isn't doing anything for the conduction--though it may be very significant with respect to mechanical properties--how well an antenna element supports itself or holds up in the wind.

Qualitatively, the skin depth:
--is GREATER (thicker skin) for poorer conductors
--is LESS as frequency increases
--causes INCREASED resistance as frequency increases
These effects go as the square root of DC conductivity and frequency, so for example aluminum has about 1.53 times the resistance of copper (depending on alloys...), but that results in a skin depth in aluminum that's about 1.24 times THICKER in the aluminum, so the RF resistance of aluminum is not 1.53 times the RF resistance of copper, but only 1.24 times as great. And for a given RF current in a wire (like in coax), if you double the frequency, the I^2*R loss goes up only 1.41 times, not 2 times. All that assumes that you're at frequencies high enough that the wire or conductor is much thicker than one skin depth.

For visualization, it's also useful to think of the current tapering off exponentially as you go into the conductor from the surface, so at one skin depth, the current density is 1/e = 37% as much as it is at the surface.

If you happen to have a very thin conductor, like your aluminization, much less than one skin depth thick, then the current density in it will be essentially independent of the depth into the conductor. Other effects may (very likely will) cause the current density to not be uniform over the width of that very thin surface, but that's another matter. For example, current in a wire in a coil, or in a parallel-conductor transmission line, is not distributed uniformly around the wire because of interaction with current in the nearby wires. See "proximity effect."

Does that help, or is there more to your "personal puzzle"?

Cheers,
Tom

We are not talking about the magnitude measurements right now.
We are talking about the phase measurements. What good does
it do to use a signal, whose phase is fixed, to measure the phase
shift through a coil or through a wire.

The phase is constant along the wire with or without the presence
of a coil. Why then is a phase shift of zero on both sides of the
coil surprising? And of what importance is that measurement?

I have an assortment of toroids of various materials from Amidon. I'm
at work right now and I don't remember if I used 43 or F material.

> On six meters, it would take a darned small probe and indicator to not
> greatly perturb the system.

They are small toroids. I chose 6m because the dipole area was
physically small.

> If I was going to test something like this, I'd use a small indicator
> hanging from the antenna and do it on a low frequency.

Please feel free to make that measurement. W7EL just reported that
EZNEC agrees with my phase measurements. So does Kraus.

> So, tell us about the probe and indicator.

Similar to the ones W7EL used. They were calibrated within one turn
of each other. The signals at the ends of the coax lines were calibrated
for equality in magnitude and phase. Magnitudes are a relative measurement
but phase was not. I ran the experiment two ways.

One was Lissajous figures on my 100 MHz Leader. The other was putting
the two samples in opposite phase to each other, i.e. phasor subtraction.
For small angles, the angle is equal to the sine of the angle so the
addition
of two coherent sine waves yields an amplitude proportional to the phase
difference when the phase difference is small. The phase difference was
so small it was virtually undetectable.

Hi Tom,

As it goes to infinity? Indeed, there are conductors and charged
bodies much closer than that to your wire in space.

However, let's look at the implications using your same formula,
except we will move L to conform to your 15 meter specification:

C = 2 ï¿½ Pi ï¿½ epsilon0 ï¿½ L / (ln(b/a))
a = 1m (after all, thin is relative at infinite dimensions)
L = 15m
b= 1,000,000,000,000,000,000,000,...000m (10ï¿½ï¿½ï¿½ meters away)
epsilon0 = 0.00000000000885

C = 12 femtofarads

This was certainly at the limits of my usual Capacitor Bridge to
measure to this resolution 30 years ago, but time has marched on. This
sized capacitance is certainly encountered every day in my new field
of nanotech, and 1 femtofarad is measured by charge transfer
techniques.

Consider, Einstein's estimate of the radius of the Universe is roughly
10 Billion Light Years (ï¿½3dB) As this result above is vastly further
away than Einstein's guess (by more than 300 orders of magnitude),
lets look at again from his number:

C = 12.5 picofarads

Oddly enough, this value is on par with the distributed capacitance of
the coil's we've been pounding away on (and even more convergent, is
this is roughly the same amount of wire used in them).

Cecil,

The phase is uniformly zero, so the phase shift is also zero.

Your messages seem to imply that there is some sort of characteristic "phase shift" in a loading coil. Ain't so.

In the example of a standing wave antenna the phase shift is zero, both experimentally and theoretically. (Approximate. Real world conditions might cause small non-zero shifts.)

If you place this same loading coil in a traveling wave antenna you can undoubtedly measure some sort of phase shift. (Exact amount left as an exercise for the student.)

Bottom line: Any characteristic, such as phase, that explicitly depends on the wave nature of a signal needs to be referenced to that condition, not some arbitrary setup.

It's likely that quite a number of people don't realize that there's no phase shift of current or voltage along a short or open circuited lossless transmission line -- except for, like on an antenna, periodic polarity reversals.

Thanks, Gene. What was implied is what has been reported as fact
by others - that the zero phase shift on both ends of a loading coil
measures the delay through the coil to be close to zero.

> In the example of a standing wave antenna the phase shift is zero, both
> experimentally and theoretically. (Approximate. Real world conditions
> might cause small non-zero shifts.)

Please note that the phase shift in the wire is also zero. That the phase
shift is measured to be zero in a coil or a wire in a standing wave
environment is not of any practical importance whatsoever.

> If you place this same loading coil in a traveling wave antenna you can
> undoubtedly measure some sort of phase shift. (Exact amount left as an

That was the discussion involving Dr. Corum's papers and the VF of
large RF inductors, like a 75m bugcatcher coil.

If we have 45 degrees of transmission line and measure no phase
shift at each end of that 45 degrees, does that mean the transmission
line is really zero degrees long?

If we have an unknown number of degrees of coil and measure
no phase on each side of the coil, does that mean the coil is
really zero degrees long?

Cecil,

You're a sly one, but not quite sly enough. 8-) 8-)

What is the meaning of "delay" in a standing wave antenna? Delay, like phase, depends on the environment.

The measurement results reported by W8JI a few days ago stand on their own. He described the setup and measurements adequately.

If you choose to make extrapolations to another environment, have at it. Just don't expect anyone else to automatically agree with your extrapolations.

As I recall, this three-year saga started with consideration of a loaded mobile antenna, which I believe would be considered a standing wave antenna. Have you since equipped your steed with a Beverage or rhombic? Are phase shifts and delays now important?

73,
Gene

They may be small toroids, but what do they connect to? What is the
common mode impedance of the indicator at 50MHz?

You may not have been measuring anything like you think, in particular
voltage. Just because EZnec agrees with the phase measurements it
doesn't mean the current measurement was even remotely close to being
correct.

> > So, tell us about the probe and indicator.

I you hung coaxial lines off a current transformer on a 6-meter dipole
down to some test instrument, you wasted a lot of time. There isn't any
possible way you measured an unperturbed system.

You'd better reconfigure as a monopole, and do it on a lower frequency.

> One was Lissajous figures on my 100 MHz Leader. The other was putting

> so small it was virtually undetectable.

I wouldn't trust that system at all.

Even with the equipment I have and having build hunderds of sampling systems, I'd never attempt a measurement like you just made.

You brought a pair of long coaxial lines that are grounded at the far end up to within an inch of the antenna, hung what amounts to being a capacitor between the high voltage high impedance side of the antenna to ground, and presumed to measure voltage and current on six meters!

You can get away with a toroid on 80 or 40 meters if the test gear and lines are all near ground potential along with the point of the antenna you are measuring, but it is really off the wall to assume you can hang a toroid on a dipole past a loading coil, have that toroid connect to a cable hanging in air down to some test gear, and not severely perturb the system. Worse yet, the test was done on 50MHz!

I used a very small floating probe with NO earth path and the indicator right on the probe. I had to do that to not perturb the system on 40 and 80 meters. I can't imagine trying to do what I did on six meters, I'd have needed an entire metering system the size of a half-dollar or smaller.

Making a measurement at the base of a vertical on a low frequency like Roy did allows the person making the measurement to get away with lots of things, but I can tell you right now I'd NEVER be able to measure anything in a short mobile antenna if I ran cables up to the probes, in particular if I made the test on six meters!

ALL coils are distributed in space. They have a conductor. Therefore they can be analysed in the same manner as transmission lines.

They ARE transmission lines, no matter what length. They can't help it!

Program COILINE demonstrates how a simple coil-loaded vertical antenna can be designed by using classical transmission line mathematics.

Enter length, diameter and number of turns on the coil, the length of the top rod or whip or wire, and you can examine how the thing behaves at any frequency. You can design anything from a bottom loaded long wire to a helical for 160 metres.

Coils can vary between a few turns on an empty toilet roll tube to a 4 feet long, 1 inch diameter, plastic pipe wound with 1000 turns.

You can prune the whip to obtain resonance at a given frequency without having to go out in the freezing cold back yard.

Discover the velocity factor, nano-seconds per meter, and other numbers for your particular coil. All will be of interest to the participants in the interminable civil war still raging on another thread. Ammunition galore!

Download program COILINE from website below and run immediately. Only 47 kilo-bytes. Its quite entertaining.

By the way, it has just occurred to me, I forgot to include coil Q in the results. But it hardly matters - there's little to be done with the number even if you know it.

Well the main thing I was unaware of is skin depthis basically non existant if the
conductori is less than two skin depths i,e,one skin depth each side and I find that inportant. So I now get to the next question, can one compensate for radiation purposes
by increasing the width of this aluminum skine to compensate for lack of material thickness? Looking at it a different way, instead of having a dipole with ithin wire
I use aluminum metalised sheet about 12 inches wide but with a skin depth of onre tenth
of the skin depth required for 180 meters.(say skin depth for 180 meters is 1 mil and the material i am using is only one tenth of a mil)
As you can see I recognise that skin depth
must also be looked at in square mills for current carrying capabilities. for an equivalent frequency range similar to when one uses litz wire.
Put another way, can on use conductors one tenth of the thiknes of litz wire and increase the number of strands used by ten times to maintain the same crossectional area but composed of strands of the skin thickness norm for the frequency of use?
As an aside skin depth also means contra flow levels of current flow is this non existant
where skin depth is lacking. Hard for me to fully understand skin depth when I take more than a cursury look.and where a little knowelenge becomes a danger!

You can compensate for the loss, yes, by increasing the surface area. The way you reduce loss is to provide a large cross-sectional area for the current to flow through.

Looking at it a different way, instead of having
> a dipole with ithin wire
> I use aluminum metalised sheet about 12 inches wide but with a skin
> depth of onre tenth
> of the skin depth required for 180 meters.

This is the second time you've referred to a skin depth "requirement". I don't understand why the application requires a particular skin depth. If you need a particular skin depth at a particular frequency, the only way to get it is to alter the conductivity of the material.

(say skin depth for 180
> meters is 1 mil and the material i am using is only one tenth of a mil)

If that is the case, then you can forget about skin depth and treat the problem as though it were DC, because the current will be essentially uniformly distributed through the conductor as it is at DC.

> As you can see I recognise that skin depth
> must also be looked at in square mills for current carrying
> capabilities. for an equivalent frequency range similar to when one
> uses litz wire.

I don't understand this. Litz wire functions in its special way only up to a few MHz. Skin effect occurs at all frequencies.

> Put another way, can on use conductors one tenth of the thiknes of litz
> wire and increase the number of strands used by ten times to maintain
> the same crossectional area but composed of strands of the skin
> thickness norm for the frequency of use?

Sorry, I don't understand the question. You should be able to find ample information about Litz wire on the web.

> As an aside skin depth also means contra flow levels of current flow is
> this non existant
> where skin depth is lacking.

?

Hard for me to fully understand skin depth
> when I take more than a cursury look.and where a little knowelenge
> becomes a danger!

It's really fairly simple. Nearly any electromagnetics text does a good job of explaining it.

Litz wire is a good deal more complicated, though, since its operation depends on more than skin effect. I imagine that a rigorous mathematical treatment has been done on it, but I'll bet it's not simple.

Gene Fuller wrote:
> What is the meaning of "delay" in a standing wave antenna?

Same as in a traveling wave antenna - the length of
time it takes a traveling wave signal to make it through
a coil or a wire. The lumped-circuit model assumes that
delay is equal to zero even for traveling wave antennas.

> Delay, like phase, depends on the environment.

I defined what I meant by "delay" through a coil a few days
ago. It was the delay experienced by a traveling wave
flowing through a coil or 1/2 the delay experienced by
a traveling wave making a round trip to the end of a coil
and back based on the self-resonant frequency. That's what
the velocity factor calculations were all about. Does the
0.66 velocity factor disappear when RG-8 is used as a stub?
Then neither does the 0.0175 coil velocity factor disappear
when it is used in a standing wave environment.

The cos(kz)*cos(wt) nature of the standing wave current
prohibits that standing wave current from being used to
determine the velocity factor of a coil or of a wire. The
lumped-circuit model assumes the velocity factor through
any and every coil to be *greater than unity*.

Assuming that the signal you're trying to track isn't moving around too quickly, and is "on" for relatively long times, I'd suggest a simple Yagi antenna connected to a receiver with a signal strength indicator. Rotate the antenna till the signal peaks; the antenna points in the direction of the strongest signal (usually the direction of the transmitter).

You can find Yagi design info on the web. Do a Google search for it. I'd suggest something modest, like 3 to 5 elements. The elements will be about half a wavelength long, which at 870MHz is about 1/6 of a meter or about seven inches. The whole Yagi might be a foot long. You can easily make it using PVC pipe and pipe fittings, and elements made from heavy copper wire. Be careful about having the feedline decoupled from the antenna so that the directionality of the antenna is not messed up by the feed line picking up signals.

Another poster suggested what I suppose is a Doppler scanning antenna, an array of elements switched with PIN diodes, but the complications of building such a system probably outweigh its advantages for what you want to do, unless you're going to be doing a LOT of direction-finding. Besides the PIN-switched elements, you need control/display electronics and an FM receiver.

Cheers,
Tom

I officially withdraw my measurements as evidence in this debate and instead substitute the EZNEC results, provided by W7EL, as evidence.

What does it mean that EZNEC agrees with my possibly flawed phase measurements? What does it mean that EZNEC agrees with my argument and disagrees with yours?

How does one use a signal with unchanging phase to measure the phase shift through a coil or wire? Forgive me if I'm wrong, but seems to me, you have claimed to have done exactly that. Please explain how you did that so we can judge whether your measurements were also flawed.

> But what about comparing different ways of obtaining the same
> inductance to find those with higher or lower Q?

==========

To double Q, whatever it is, just double length and diameter of the coil, wind on a number of turns of much thicker wire for the same inductance, and Bingo, Q is doubled. The value of Q is unecessary.

Efficiency and bandwidth can be deduced by calculating from the known values of wire and radiation resistances. But I suppose Q, once available, would be a short cut to crudely estimating bandwidth. Additional information is needed.

The loss in the coil may not be the dominating factor. What matters is the System Q. It can be considerably worse than coil Q.

Reg.

I expected you would want to discuss the problems of making a measurement in the high impedance part of an antenna with a toroid around the wire and a coaxial cable running down to a 100MHz scope on 50Mhz.

I see now you really only want to spew, and have no desire to learn anything.

I took the time to carefully outline what Roy's measurements and mine would be significantly more reliable, and I see you disregarded that also.

I'm very disappointed in your reaction to the effort I made to help you understand measurement techniques.

```
>
> Reg, would you care to share your formula for velocity factor?
========================================

Cec, can't you find it in your bibles?

Velocity = 1 / Sqrt( L * C) metres per second

where L and C are henrys and farads per metre.

What you really want to know is how to calculate L and C from coil
dimensions. But you won't find that from any bible.

As a special favour, I'll attach the source code for the program to an
e-mail. Read it with a non-proportional text editor such as Notepad.

In your discussions on the other thread you have mentioned a coil's
self-resonant frequency. In the source code you will also find a
formula for Fself. Which, again, cannot be found in any bible. It is
a fairly straightforward 2 or 3-line formula.

Fself is not used anywhere in the program. It is available solely out
of interest. It is fairly accurate. I have measured it on many coils
of all proportions and numbers of turns from 1 inch to 6 feet long
with 1500 turns.

Thanks for the quick response
I have not seen mention in any books that skin effect can be ignored in
some cases which was good info.
You confirm what now can be seen as tuintive that what initial was a
depth/area definition can also be seen as a
volume question which rearly was the reason for the posting.The only
reason I used the Litz wire scenario
was because I recocognise that some had diffuctu with
the originak question that I tried to put numbers with it.
A follow up qurestion would now be if an element was
made of a skin fashioned from aluminised mylar using a comparitive
aluminum volume aproach would any changes in radiation efficiency
weould occur?
As a side note the contra current flow that I refferred to
was what it appears various straas of current flow that one sees
illustrated in text books would change radiation
as one aproaches a sigle strata where their is no contra flow, but let
us put that aside for another day.
As another aside I have made an apparatus where I have placed to
parallel wires inside a glass tube (flourescnt
lamp tube where I can draw a vacuum with some dust inside the tube so
the point of static flow can be observed
and then observe the cross over point when using thin
aluminised strip in the hope that for the same frequency
the same cross over point will be seen as the same.
Best regards
Art

w8ji@akorn.net wrote:
> I took the time to carefully outline what Roy's measurements and mine
> would be significantly more reliable, and I see you disregarded that
> also.

You demanded that I defend my measurements so I removed them
as evidence. Now I am requesting that you defend the use of a
signal without phase to measure phase through a coil. That's
a very simple request. If one refuses such a simple request
to defend one's methods, what is one to think?

I gave up on my measurements rather than defend them. If you
don't defend yours, are you automatically giving up on them?
If no, one might then wonder why you require me to defend my
measurements while you refuse to defend yours.

Gene says standing wave current doesn't carry any phase
information. I concur. Roy says EZNEC agrees with my possibly
flawed measurements. I concur. Since EZNEC disagrees with your
conclusions about your measurements, and agrees with my conclusion
about your measurements, could your conclusions possibly be
flawed? I'm sure many readers would be interested in a
detailed explanation of exactly how to use a signal with
unchanging phase to measure the phase shift through a coil.
I certainly would be more interested in that explanation
than a boring tutorial on measurement techniques. Heck, even
the IEEE would be interested in such a unique technique and
it might even be patentable.

You could start by explaining the center graphic in the following:

http://www.qsl.net/w5dxp/3freq.gif

One can't help but notice your absolute silence on that subject.

> I'm very disappointed in your reaction to the effort I made to help you
> understand measurement techniques.

<humor> Reminds me of a T-shirt I saw. It read, "I'm from the
government. I'm here 'to help you'." </humor>

Logical diversions are very transparent - they even have names.
That one is called "diverting the issue". The issue is not my
measurements since I have withdrawn them as evidence. Seems
that automatically makes your measurements the subject of the
discussion.

Well now, W7EL, a pretty smart fellow questioned that equation,
as I remember before a bottle of CA Sutter Home Cabernet Sauvignon,
circa 2001. (Not bad for a 5 year old red.)

Dr. Corum's equation is a mite more complicated involving
fractional powers of diameter, turns per inch, and wavelength
and it closely agreed with my self-resonant measurements.

If we work backwards from Dr. Corum's fairly accurate
VF, can we calculate the L and C of the coil?

>. . .

What seems to be getting lost in the discussion is that L is *series* L per meter and C is *shunt* C per meter -- that is, the C to another conductor(*). C is not the self-capacitance of the inductor.

(*) Conductors also have capacitance to free space, but I'm not at all sure the transmission line equations for such things as velocity are valid if this is used for C. The equation for the resonant length of a wire in space is very complex and can't be solved in closed form, and even approximate formulas are much more complex than those for transmission lines. So while transmission lines and antennas -- or radiating inductors -- share some characteristics, you can't blindly apply the equations for one to the other and expect valid results.

Guess I missed that posting. Current isn't stratified in a homogeneous conductor. But it sounds like some good stuff to use in explaining why some antenna or other has magical properties that have defied all the conventional thinkers for generations.

That makes no sense to me either. Time to pass the baton to someone who can understand what you're saying.

I didn't demand anything. I asked what equipment and frequency you
used.
When you told me, it became very obvious you could have made a much
more reliable measurement.

I'm suprised you wouldn't want to learn more about measurements.

I don't see anything Roy said that disagrees with what I measured, so
that's a non-issue.

I take it you don't want to discuss how to make better measurements?

I don't understand what it is and how you "constructed" it. Maybe you can explain.

Did you build one and verify the results? I've never seen a coil loaded antenna work on three exactly even harmonics without special manipulation of lengths. That would make an interesting antenna if you could just make it any length and any coil and have it work on harmonics.

Doesn't the change in distance between a pair of current nodes (or voltage nodes) in the standing wave pattern on a straight conductor that straddle an inserted inductor show its effective electrical length? I would think that as long as a fairly pure standing wave could be arranged with the inductor inside it, this method would allow the effective electrical length to be measured at arbitrary frequencies that are not at all related to the coil's self resonant frequency. It seems that this is nearly what you are demonstrating with your EZNEC examples. Electrical length (propagation distance) is collapsing into the inductor.

The problems I have with this approach is that the larger conductor
(only the outside of which is contributing to conductivity) is
blocking the path of more and more flux, crowding it into the space
that is left. It is a matter of gaining some and losing some
(hopefully less).

Cecil,

I have to admit I am mostly lost about the meaning in your post below.

However, nothing in my comments was intended in any way as support or denial of the measurements presented by Tom, W8JI. They look proper to me, but I am not an expert on such measurements.

This entire thread is quite bizarre in that all sorts of special cases are being debated (Tesla coils????) while the simplest basic level of standing wave behavior is overlooked and even challenged.

I suppose that's typical for RRAA.

I'm surprised you wouldn't want to share your engineering
knowledge, e.g. is it really possible to use a phaseless
signal to measure phase shift? If so, please enlighten us.
I can't figure out how to do it. Since you apparently have
figured it out, please share your knowledge with us.

> I don't see anything Roy said that disagrees with what I measured, so
> that's a non-issue.

Roy and I have previously agreed with your measurements. It's
your conclusions about those measurements that he apparently
doesn't seem to understand and neither do I. I'm certainly not
speaking for Roy, but when he points out to you that my
measurements agree with EZNEC, one wonders what that means
in reality.

> I take it you don't want to discuss how to make better measurements?

I take it you don't want to share you knowledge of how to
measure phase using a phaseless signal? Such a feat is
extremely more important than any measurement discussion.

Please just explain from a technical standpoint how a
signal without phase can be used to measure a phase
shift through a coil. That's an extremely simple request
and would be extremely useful to the entire group.

While you are at it, please explain the EZNEC results
in the middle graphic at: http://www.qsl.net/w5dxp/3freq.gif.
the request for which you seem to have forgotten about.

I simulated a typical vertical base-loaded coil system using the
helical coil feature of EZNEC. I found the resonant frequency and
displayed the results in the left graphic. I then left everything
else alone while I multiplied the resonant frequency by 2 and
displayed the results in the middle graphic. I then multiplied the
resonant frequency 3 and displayed the results in the right graphic.
It's a no-brainer. Have you never done such with EZNEC?

Would someone, somewhere, please explain the ~0.2 amps at the
bottom of the coil in the middle configuration Vs the ~2.0
amps at the top of the coil? Is EZNEC reporting bogus results?

L and C are neither in series or in parallel with each other.

They are both DISTRIBUTED as in a transmission line.

To calculate the self-resonant frequency what we are looking for is an equivalent shunt capacitance across the ends of the inductance.

Turn to turn capacitance is is a very small fraction of the total capacitance. If there are 10 turns then there are 10 turn-to-turn capacitances all in series. After a few turns there is very little capacitance which can be considered to be across the coil.

Consider two halves of the coil. We have two large cylinders each of half the length of the coil. Diameter of the cylinders is the same as coil diameter. Nearly all the capacitance across the coil is that due to the capacitance between the two touching cylinders (excluding their facing surfaces).

The formula for VF is true for any transmission line with distributed L and C. And a coil has distributed L and C.

Agreed, L and C are approximations for very short fat coils. But any approximation is far better than none at all. All antennas have to be pruned at their ends.

Please explain how that could be possible with constant
magnitude and phase of the currents through the coil.
The magnitude and phase is absolutely constant according
to the presuppositions of the lumped-circuit model. How
could it possibly collapse?

How about his conclusions about those measurements?
Maybe you can help him out. How does one measure the
phase shift through a coil using a signal that doesn't
support phase? If there is a way, I and others would
certainly like to know about it. So far, I confess
that I haven't been able to figure it out.

Ok, I have had a thought. And I had to go back to where everyone, starting with Cecil, was talking about or responding to a constant delay through the coil.

Picking a nice round number, say 55 degrees, I would then need 35 degrees of whip above that coil to make a quarter wave resonant antenna, correct?

So, it should work just as well, using Cecil's reasoning, if I displace that coil to another position. He did measure the coil as a standalone device which causes a fixed delay, correct?

Ok, so now I move that coil up the antenna, not much, say 2 degrees. Now I have 2 degrees below the coil, and 33 above it. It will still be resonant, right? Now I move it another 2, and another and another, until it it at the top, with no stinger. With the reasoning I have heard from Cecil, it will always be resonant.

It looks like various magnitudes that you would find at 2 points along
a standing wave, with various fractions of the wave in the inductor as
frequency changes. In spite of hitting these various magnitude
values, there are still only two phases, 0 or 180 anywhere outside the
coil. In some cases, the standing wave goes through a node, inside
the coil and reverses phase from one end of the coil to the other.

No, that is a myth spread by some people as a strawman
argument. Please don't support that strawman.

The requirement for resonance at the feedpoint is that
the phasor sum of the forward and reflected voltages
be in phase with the phasor sum of the forward and
reflected currents. Therefore, 90 degrees is *NOT*
required in the round trip. Indeed, the round trip
for the voltage doesn't have to be the same number
of degrees as the round trip for the current. That is
a misconception spawned by the lumped-circuit model
where everything is perfect and waves travel faster
than the speed of light. The real world is not so
perfect.

Given that the resonant feedpoint impedance equals
(Vfor+Vref)/(Ifor+Iref) isn't it obvious that the
individual components are not required to have the
same phase? For instance, Vfor could be at +50 degrees,
Vref could be at -40 degrees, Ifor could be at +20
degrees, Iref could be at -10 degrees, and the feedpoint
impedance would still be resistive.

The coil distorts the heck out of the phase relationships
between the voltages and the currents. Why is it surprising
that the result is unpredictable and needs an antenna
analyzer to find the resonant frequency? Factor in that
the lowest 50 ohm SWR may not be at the purely resistive
point and what do you have?

Exactly! Now please explain how the nS delay through a coil
could possibly be measured using a signal that abruptly shifts
fixed phase by 180 degrees every 180 degrees.

Of course I understand that both L and C are distributed. But the C in the transmission line formula isn't a longitudinal C like the C across an inductor; it's the (distributed, of course) shunt C between the two conductors of the transmission line. I don't believe you can justify claiming that the C across an inductor is even an approximation for the C from the inductor to whatever you consider to be the other transmission line conductor.

I'm sorry, I don't understand this. Can you elaborate? In what way does increasing a wire's diameter block the path of existing current and cause crowding? When a wire's diameter is at least many times the skin depth, the RF conductivity of the wire is directly proportional to the surface area of the wire, hence to its circumference or diameter. So in what way does this blocking and crowding manifest itself, and what would be the relationship between area and conductivity if it didn't occur?

Wanna bet?

The phase shift along the coil plus the phase shift along antenna conductors does NOT add up 90 degrees when the antenna is 1/4-wave resonant. It is not anywhere near to it.

I think you are the one with a problem, not me. I don't know what a
"phaseless" signal is. Does it come from a phaseless signal generator
through phaseless transmission lines??

I haven't seen Roy question anything and he hasn't told me he doesn't
understand anything.

Can you requote his post where he said that, or should I take your word
for that along with the phaseless signal??

Agreed. They are as different as a shunt element and a series element
in a pi filter.

That.s O.K. Roy, you at least was able to answer the main questions I had
On the last part where I refferred to an elemement that were capacitively coupled to each other by an overlap the energy jump over point can be shown by statically charged dust.
(at least I believe so) and this point would change if frequency changed or the characteristic change with the introduction of un-equal element current characturistic.
At the moment I have a leak somewhere so the vacuum is not constant. I feel pretty sure
of what I will see initiallly, so armed with what I have gained on this thread I can head directly to an equivalent volume aproach when changing over tosing ultra thin material for
the first part of the element.(The element will be a short vertical within a vacuum that way the statically dust will chaege and the field characteristics easilly seen...I hope) I will use whit/e powder so the cross over field point will be measurable in the same way iron filings are used with a magnet.. I can easily see why you can.t follow in visualising what I am about to do as you are rather rigid in thought which is O.K.Especially if you refute the idea
of visible static charges illustrating a field of sorts. The above thoughts came about in a hospital bed where in the absence of a new British heart I had to have a lot of scraping done together with the maximum number of bypasses plus an electrical thumper to keep all things going plus a longer than normal stay in bed.with a wandering mind. I suppose I could have opted for a new american heart but I concluded that a renovated British heart would remove the necessity of another operation to add more guts to make up for the inbalance.All this came about shortly after my gall bladder burst without warning

The only way I can see to do it is to go outside the coil and look at
how the standing current nodes move. Standing wave phase is with
respect to position, not time.

The first problem is that the phase shift along the antenna is about zero. Having the phase shift along the antenna and coil add to 90 degrees would require a 90 degree shift of current phase across the coil, regardless of the size of the coil or the antenna. Only the inductor in an EH antenna drive system has that magical property. I assume you have to empty the internal coulomb bucket periodically, but I'm sure that's proprietary.

Pluck a guitar string and watch it oscillate. Notice that all parts of the string reach their maximum and minimum excursions at the same time. There's no delay from one point to another. Same thing happens on a (standing wave) antenna or a shorted or open transmission line, and for the same reason.

Take it to the extreme case. make the conductor diameter the average
coil diameter. Then there is little space for the total coil flux to
pass through.

> In what way does
> increasing a wire's diameter block the path of existing current and

(snip)

It doesn't block current, it blocks flux from other turns of the same
coil, reducing the inductance and lowering the Q.

I am thinking that there must be a better conductor cross section than
a big fat round cross section, a ribbon, perhaps, aligned edgewise to
the local flux, to increase the conductivity while not blocking much,
the coil flux.

"Phaseless signals". What an imaginative creation. If you measure zero phase angle between two points, you *have* measured the phase shift between them, and it's zero. Sounds like what Cecil is looking for is a way to measure a non-zero phase shift when the phase shift is in fact zero, to make it fit his theory. Sorry, it's zero. Period. If that doesn't fit the theory, then the theory is faulty.

I said that Cecil's phase measurements agree with EZNEC (and generally accepted theory) -- there should be almost no phase shift in the current along the wire. I also said that I couldn't say whether his amplitude measurements are correct, since Cecil didn't say (at least in the quoted posting I saw) what the positions along the wire were, just their distance from each other. But it's a trivial thing to model with EZNEC, so anyone can easily see and judge for himself. With an antenna that simple, any disagreement between EZNEC and measurements is almost

certain to be due to either measurement error or failure to make the antenna like the model, e.g., prevent common mode feedline currents.

Thanks for the elaboration. I didn't realize you were talking about the wire used to make a coil, but thought you (and Art) were talking about skin depth in conductors in general. The discussion gets much more complex when talking about an inductor with its linked flux.

Even when there's no flux coupled from other turns, current bunches at the edges of a flat conductor, giving it a higher resistivity than a round conductor of the same surface area. So that's a point against using a flat conductor, although other factors might -- or might not -- still tilt the balance in its favor. Proximity effect is another factor which alters current distribution and therefore resistivity and Q in an inductor, so there are a number of trades to be made.

I don't understand what you are trying to say. Express yourself, less ambiguously, in fewer words.

Or perhaps you are nit-picking. I can't tell.

I have just explained that the resulting capacitance between adjacent conductors in a coil is very small in comparison with the capacitance of a large solid cylinder (of the same diameter as the coil) to the rest of the world.

The capacitance to the rest of the world includes electric lines of force from one half of the cylinder to the other, especially from one end to the other. The capacitance of the coil we are dealing with has very little to do with coil turns.

Reg.

I apologize, but I actually have to plead complete ignorance on
this subject. You seem to be the expert on using phaseless signals
to measure phase. But I'm willing to learn and it is certainly
considerably more interesting than a tutorial on measurements.

> I haven't seen Roy question anything and he hasn't told me he doesn't

>
> Can you requote his post where he said that, or should I take your word
> for that along with the phaseless signal??

Please stop asking me to do your research for you. I'm a very
busy person anchoring the bass section in my Methodist Choir's
Easter music and performing a very demanding solo. Have you any
idea how difficult it is for a Homo Sapien to hit low-low C?

Roy said about my measurements:

"The measurement looks good to me. The phase is exactly what EZNEC predicts
-- constant along the wire. The ratio in magnitudes we'd expect depends on
the positions along the wire, not just the spacing. Roy Lewallen, W7EL"

That's why I withdrew my "flawed" measurements and offered Roy's
"exactly" observation instead.

I'm thinking back and it seems to me that Roy reported his
measurements without drawing strange conclusions about them.

But you can lay all the objections to waste simply by explaining
how to measure phase using a source signal that doesn't change
phase. You have asserted that you have done it. Please tell us
how.

2947. Looking to contract someone to design antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-17 04:31:55 UTC
From: David <dhuisman@bigpond.net.au>
Message-ID: <%YqSf.8491$dy4.6755@news-server.bigpond.net.au>
Source record: 62908

Hi,

I am looking for someone who would be interested in designing a Yagi antenna under contract. (Paper design is fine, I can construct and test the unit).

The frequency band required is 915 - 928 MHz

I prefer a design that is simple to make such as elements though beam, welded in place.

The design needs to be reasonably short (Beam length less than 300mm).

The material I have freely available is 6mm solid aluminium rod (and larger if needed), 12.8mm square aluminium tube (or larger if required) but have difficulty obtaining smaller than this.

Power handling is not critical as max. power is 1 Watt.

Units will be used in vertical orientation and beam width is not critical.

Required gain is at least 6dB (4 or 5 element should suffice).

Feed line is 50 Ohms coaxial cable.

SWR across band target < 1.4 : 1

Maybe folded element would be the simplest to match to with a balun even though I have to create the bends. I expect the dipole can be held in place by small plastic enclosure that isolates the radiator from the beam and enables connections to balun and feed line via cable glands ?

Please email me direct if you are interested.

Thanks

regards

David

Well not really, if you think about it, the phase of a DC signal can be considered to be zero everywhere. The phase of a standing wave current *is* zero everywhere on a 1/2WL thin-wire dipole. Seems to me, a standing-wave current indeed does have a lot in common with a DC current. But that might just be a coincidence. :-)

Thank you. I guess I would need a 3D finite element analysis program
to explore skin effect in coils made of arbitrary cross section
conductor (dog bone shape, for instance).

Is proximity effect essentially the effect of the local flux (that
falls off at 1/r) that wraps around the neighboring conductor in a
coil that causes conductivity distortions in its neighbors that are in
addition to the crowding caused by the flux around the current through
the conductor segment in question? Or is it another effect, entirely?

Look up the Turnstile antenna on the web and you should see the
radiation pattern of a 90 degree phase shift. There is also a small
amount of gain over a single dipole.
Most examples are for VHS, but they can be scaled up.

I believe what you're describing is the cause of skin effect. Proximity effect is a redistribution of current around a conductor due to the flux from one turn interacting with the current in the adjacent turn. One of the simpler explanations I've seen is in Johnson & Graham, _High-Speed Signal Propagation: Advanced Black Magic_, and their quantitative and non-mathematical explanation requires seven paragraphs and two figures.

They are not entirely separate effects, because more localized
flux/current interactions will be causing a skin effect as well. We can
separate skin and proximity effects for convenience in thinking about
them, but they will interact to some degree.

(It's a lot like thinking about yagi antennas, where it's generally
understood that every element has interactions both within itself and
externally with every other element.)

Yes, it sounds that way to me also.

It sounds like Cecil is trying to find a way to make his theory fit despite the fact that models and measurements show the phase shift is zero, and demanding I agree with his unusual theories like current that doesn't flow, phaseless signals, and in his latest post antennas behaving like dc circuits.

> I said that Cecil's phase measurements agree with EZNEC (and generally
> accepted theory) -- there should be almost no phase shift in the current
> along the wire. I also said that I couldn't say whether his amplitude

> distance from each other.

Knowing a little bit from direct experience with probes and measurements, I would't trust use of a toroidal transformer stuck on the high impedance end of a dipole loading coil and coax hanging down to a 100MHz oscilloscope. Not only does he have a pair of long transmission lines hanging down, the system is on 50MHz where any small capacitances can totally hose results.

Anyone who has tried to make a current transformer in traditional HF style with a toroid behave correctly on VHF will understand what I am saying.

All that aside, it appears the main argument is Cecil's theory requires measuring current that doesn't flow and a signal magically generated with phase that cannot change. The worse part of that is he is demanding I answer something I cannot answer (phaseless signal, and current that doesn't flow), so I guess I''ll just have to settle for my share of the 3 million dollar theory and leave.

Again, it is not my theory. It is the distributed network model
known to succeed when the lumped-circuit model fails in the presence
of standing waves. There is no useful phase information left in
a standing wave current. DC current and standing wave current are
equally 100% ineffective at measuring the delay through a coil.

I have asked this technical question multiply times: How does one
use a signal with unchanging phase to measure the delay through a
coil? The answer is that one cannot.

> All that aside, it appears the main argument is Cecil's theory requires
> measuring current that doesn't flow ...

No, using a signal with unchanging phase to try to measure delay
is your main argument, not mine. I know it is foolish to measure
a current with unchanging phase. Any phase measurement is
meaningless.

cos(kz)*cos(wt) doesn't possess phase information. One can
tell that from the formula. Unlike you, Gene Fuller understands
the meaning of those standing wave equation terms.

Do you disagree with what Gene had to say?

"PHASE IS GONE. KAPUT. VANISHED. CANNOT BE RECOVERED. NEVER TO BE
SEEN AGAIN." In other words, one cannot use standing wave current
to measure the delay through a coil. Delay doesn't exist in a standing
wave current, i.e. "PHASE IS GONE."

> The worse part of that is he is
> demanding I answer something I cannot answer ...

There's nothing wrong with admitting ignorance. Just please cease trying to disguise your ignorance as some technical fact. When are you going to correct the technical errors on your web page?

75m mobile bugcatcher loading coils possess a velocity factor of approximately 0.0175. They are about 6.6 inches long. The delay through that coil is ~0.128 wavelength at 4 MHz. That's a delay of 32 degrees. That's how much electrical length the coil is occupying when it is used on 4 MHz.

2961. Coil Current Summary

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-17 14:02:06 UTC
From: Cecil Moore <mycall@arrl.net>
Message-ID: <yjzSf.61103$dW3.19208@newssvr21.news.prodigy.com>
Source record: 62922

Here are some valid conclusions that can drawn from the
"Current through coils" thread.

A mobile antenna is a standing wave antennas. Some mobile
antennas use loading coils within that standing wave
environment.

There is no useful phase information in standing wave
current. Therefore, standing wave current cannot be used
to determine the percentage of a wavelength that is
occupied by the coil.

Standing wave current cannot even be used to determine
what percentage of a wavelength is occupied by the whip
above the coil. Standing wave current has virtually
unchanging phase the entire length of the mobile antenna.

The percentage of a wavelength occupied by any element
can be estimated using that element's velocity factor.
The velocity factor of the whip is known. The velocity
factor of the coil can be measured or estimated using
applicable formulas.

The presuppositions of the lumped-circuit model render
it ineffective in any attempt to analyze large coils
in a standing wave environment. Either the distributed
network model or Maxwell's equations must be used to
obtain valid analysis results.

An answer that is completely wrong is better than no answer at all?

Speaking of answers, here is a question to which you have, so far,
avoided giving an answer.

In the graphic at: http://www.qsl.net/w5dxp/3freq.gif , the currents
in the center graphic reported by EZNEC are:

The current at the bottom of the coil is 0.17 amps with a phase angle
of -1.72 degrees.

The current at the top of the coil is 2.0 amps with a phase angle of
-179.6 degrees.

The current at the top of the coil is about 12 times the magnitude of
the current at the bottom of the coil.

The phase shift through the coil is about 178 degrees.

Once again, please explain those results. Thanks in advance.

Reg wrote:
"Wanna bet?"

Don`t bet against Reg.

Phase shift aling the coil plus the phase shift along the conductors DOES add up to 90 degrees when the antenna is 1/4-wave resonant.

Recall the purpose of the coil is electrically to make the too-short whip appear full-sized.

The assembly is resonant when worked against the earth. Its plus and minus 90-degree reactances are equal in magnitude to each other.

Best regards, Richard Harrison, KB5WZI

Cecil,

I never in my wildest dreams said anything about Tom's measurements.
(Perhaps in your dreams.)

I don't believe that Tom set up a simple standing wave antenna and then
tried to measure the phase of the standing wave.

You seem to have forgotten, but a few days ago you were vehemently
arguing that the bugcatcher coil in your mobile antenna must have X
amount of phase shift. My comments, which may have proven too
successful, dealt only with the basic fundamental properties of waves.
That's the sort of thing that everyone should have learned in elementary
school, but such knowledge seems to be fleeting for some people.

Cecil,

1. I have looked at that figure, and I suspect many others have as well. There is no information given about dimensions or any other modeling conditions, so it is difficult to say anything more than, "Yep, there's a bunch of lines and numbers on that figure."

2. As I pointed out recently, a phase shift of 178 degrees is really a phase shift of 2 degrees. It is a common, but unfortunate, convention that the ordinary sign reversal of a sinusoidal function is deemed a "phase shift" or "phase reversal". The only "phase" worth discussing is the one that occurs inside the argument for the sinusoidal function. That phase does not typically undergo sudden jumps or reversals.

Hi Roy,

I have been away for awhile so haven't had a chance to reply.

My point of the S meter being the same relative difference between S
units on all bands comes from the assumption that like most modern
radios, there is no AGC controlling anything in the front end of the
radio. All the gain control is done in the IF so it is impartial to
frequency.

So even if there is some difference in the gain of the first mixer, or
preamp if there is one, the gain controlled IF sees the same relative
signal level regardless of band.

I did a quick check on my old Kenwood TS430 using a Wavetek 3001
signal generator that has a step attenuator in it and got the

following results:

+60= -10dbm
+50= -20dbm
+40= -30dbm
+30= -40dbm
+20= -50dbm
+10= -60dbm
S9= -70dbm
S7= -80dbm
S4= -90dbm
S1.5= -100dbm

Test was done on 80, 20 and 10 meters with the readings the same on all bands as close as I could determine the meter reading. I would suspect that the signal generator leveling accuracy may be no better than what error can be read on the S meter.

> occupied by the coil.

I think I disagree with this. A standing wave has one of two phases with respect to time, but the two waves traveling through both the antenna elements and any loading coils do have phase shifts, both with respect to time and with respect to position. But when the two waves are superposed, all that is left of this phase information is phase with respect to position. The phase shift of both the single direction waves can be inferred by the shift in position of where they combine to form a node (if you make the (reasonable?) assumption that the delay in both directions is equal.

> Standing wave current cannot even be used to determine
> what percentage of a wavelength is occupied by the whip
> above the coil.

There is information about this in the amplitude versus position of the standing wave. But the only very definite points in this variation are the nodes, so is the length is less than a half wavelength, you have only the node at the end to work with, so you have to use the sinusoidal amplitude curve to work with.

> Standing wave current has virtually
> unchanging phase the entire length of the mobile antenna.

With respect to time, yes. With respect to position, no. The amplitude is different at different locations, so you can use phase of the wave with respect to position. It is just a bit of a mental switch to change from phase in time to phase (fraction of a 180 degree half cycle of amplitude wave from one node to the next).

> The percentage of a wavelength occupied by any element
> can be estimated using that element's velocity factor.

Or the velocity factor of the traveling waves can be measured by the interference pattern they produce as a standing wave. One cycle of the standing amplitude wave has to occupy the length that carries one cycle of the traveling wave.

> The velocity factor of the whip is known.

Lets say that it has been measured for some cases, and generalized to others.

> The velocity
> factor of the coil can be measured or estimated using
> applicable formulas.

If they apply to this particular coil construction. Or you could measure the standing wavelength with an without the coil and, so, measure the coil's "length" in standing wave (and thus, traveling wave) lengths.

> The presuppositions of the lumped-circuit model render
> it ineffective in any attempt to analyze large coils
> in a standing wave environment.

Or any other environment where they have a net delay (electrical length) that is not insignificant with respect to the frequency in question.

> Either the distributed
> network model or Maxwell's equations must be used to
> obtain valid analysis results.

Or you work with amplitude measurements versus position of the standing wave.

(snip)

I picture proximity effect this way:

The flux around a round conductor is perfectly circular and must build
up and collapse through the surface of the conductor each half cycle.
But if there is a another conductor very near, the combination of
the two fields adds up to an off center, non circular result around
the first conductor, but this must still build up, collapse each half
cycle. It just doesn't do this symmetrically with respect to the
conductor. So the skin effect in the conductor is also no longer
symmetrical around the conductor. Current is not only crowded toward
the surface, but to some parts of the surface more than others.

> I don't believe that Tom set up a simple standing wave antenna and then
> tried to measure the phase of the standing wave.

Maybe we should ask him. As I understand it, both Tom and Roy
set up a simple loaded 1/4WL resonant *standing wave* monopole
and measured the standing wave current at the bottom and top
of the coil. EZNEC could have told them that they wouldn't
measure any phase shift around the coil or anywhere else
around along the antenna..

It's an easy mistake to make to look at the current displayed
by EZNEC and picture that current flowing from the feedpoint
to the tip while being 100% radiated in the process so the
current falls to zero at the tip of the antenna. As we know,
those are not the technical facts. The reflected wave is a large
percentage of the forward wave.

As seen from the graphic at: http://www.qsl.net/w5dxp/3freq.gif

that standing wave current can have virtually any magnitude but
has a phase that comes only in near-zero or near-180 degrees
increments.

I've been asking how to obtain phase information from a
standing wave current. Nobody has answered.

I am not sure we have the exact same thoughts, but I think there are areas of agreement.

The real revelation for me, from this discussion is how the concept of "phase" takes a dimensional jump (from time to position) when you change from taking about a traveling wave to the standing wave that results from the superposition of a pair of oppositely traveling waves of the same frequency.

Source record: 62839

I don't think its quite that simple (circulator) and I'm not sure how the
circulator solves the problem particularly if it has only two ports. In
addition a circulator for 30-512 probably isn't in existence. Perhaps more
explanation is needed on this, Dan.

This depends on the actual frequencies.
A diplexer must have two non-overlapping frequency ranges to "split" in two.
Like one is 30 - 90 and the other is 100-512. Each can be quite wide.
What your post has is OVERLAPPING frequencies and that is a problem. If one
was 30-90 and the other 120-512 that would be easier. There are units that
are quite inexpensive that will do 2-150 and 200-512.

You seem to have the correct idea about the impedance "seen" at one, but at
the frequency of the other, but this applies when using some methods, not
all.

If the two radios will be operated at the same time, then the problem is
more strict in the requirements of the method used. When one transmitter is
transmitting, it puts considerable power into the system at the transmit
frequency, and harmonics as you well know, however, a transmitter also puts
out considerable NOISE all over the place. There is typically more noise
nearer to the transmit frequency. This noise must be reduced to prevent it
from desensing the other receiver and this may require additional filtering.

I know this makes things more difficult, but from your post, it looks that
way.

When the two waves combine, information is lost, just as when two DC currents pass through the same wire. You can measure the total current, but information as to what each of the original two currents were, is lost. All you can say is that the two waves add to zero at some points, and add to an alternating current (at the original frequency) at some magnitude at other points. These measurements tell you a lot about the two waves (their physical wavelength on the conductor, for instance), but it doesn't tell you enough to reconstruct both of them, completely, without some assumptions.

Please replace the above with:

There is no useful phase information contained in the
standing wave current phase measurement. Therefore,
the standing wave current phase measurement alone
cannot be used to determine the percentage of a
wavelength that is occupied by the coil. The
standing wave current amplitude measurement does
contain some implied information about the underlying
forward and reflected waves, e.g. they are equal and
out of phase at a point where the standing wave amplitude
is zero.

How's that, John?

What is really strange is that you believe what it "reminds you
of" is of technical importance. How about a technical rebuttal?
Guilt by association is an easily recognized diversion of the
issue. For the record, I argued with Chip as much as you did.
In fact, Tom, I always take your side when you are right.

Gene appears to me to be incredulous that you could possibly
believe there is any information at all in the standing wave
current phase measurement. Hint: There is none, just as Gene
asserts.

I suspect that Roy, W7EL, has discovered that same thing and
realizes that his standing wave current measurements, though
perfectly accurate, didn't provide any information that wasn't
already available from EZNEC or Kraus.

What I suspect is that neither you nor Roy realized that the
standing wave current phase is virtually constant from the
feedpoint to the tip of the antenna in a mobile antenna,
whether a coil is present or not. (When I reported the same
results as EZNEC, you implied my measurements were wrong.)
Roy said my measurements agreed with EZNEC. Is EZNEC wrong?

So when is one going to correct the errors on one's web page?

Of course, we can speak of the phase (temporal or spacial) of any periodic waveform. But it might be important to keep in mind that the spacial amplitude distribution of a standing wave isn't generally sinusoidal. When the forward and reverse traveling waves are equal in magnitude, the amplitude distribution -- that is, the "waveform" if you plot magnitude versus position -- is the absolute value of a sine function. For all other cases, it's described by hyperbolic trig functions. So the "jump" from time to position involves more than phase; it also involves a change in waveshape.

Exactly! That's why the current waveforms through the coils
are not perfect cosine waves. To maintain the same forward
and reflected power, when the phase between the voltage
and current changes, their amplitudes must change accordingly.

Conservation of energy dictates that V*I*cos(A) must remain
constant (assuming no storage) so if the (A) angle changes,
voltage and current magnitudes must change accordingly.

My basic position has been consistant for years and so
has Tom's. If you google the newsgroup from a couple
of years ago, I asserted to Roy that his standing wave
phase measurements were meaningless. I asserted that he
had measured the wrong parameter. Where were you?

Years ago, I indeed thought it was a simple problem.
I no longer think it is a simple problem. If that's
defined as "switching positions", then I am guilty.

It's simple math.

For instance, you go to the store to buy penny candy. You plunk down the penny. The grocer says there's 5% tax on sales. 5% of 1 penny ultimately reduces his options. He takes the penny and gives it to the government. You get nothing. The grocer sells nothing. The government gives the penny to a billionare as a tax refund. Deprived of your penny candy, you get to drive through pot holes as the billionare helicopters over you. To show his charitable feelings, he scatters messages of cheer and thanks to those below. You are pulled over for littering, fined $1000 and put on a trash pick-up team.

Source record: 62855

When the material is thin relative to a skin depth, the current isn't completely uniform at any frequency above DC. However, it's close enough that the resistivity is essentially the same as if it were uniformly distributed. That's why I said you could treat the problem as though it were.

I'm surprised that you couldn't find this on the web, but I'll provide a number of textual references if you're truly interested in learning more about it. Some include the necessary equations with which you can do the calculations yourself, if you've got access to tables of modified Bessel functions or a software math library which includes them.

Hmmmm, let's put this another way. Let's say you have a herd of ice cubes and you put them in a tray of oil. They sink immediately. The oil is the conductor, and the ice cubes are the charge being transferred. They sink because of buoyancy. Their weight is greater than that of the oil so this is our DC metaphor. The ice cubes use the full depth of the oil.

Now we create an AC metaphor by replacing the oil with water. The ice cubes are lighter than water, on a cubic basis, and thus they float. They cannot use the full depth of the water. The charge has been forced to the surface to conduct. You can push them underwater, but once you release them they float again. The water depth that supports them is the skin of the skin effect.

Now we create the Skin Effect metaphor. You drain the water to height that is half that of the ice cubes. The ice cubes now use the full depth of the water just as they use the full depth of the oil. However, there is less water than formerly, and less water than formerly for the oil. The skin depth is not deep enough to support the charge - resistance increases.

Oh, and if you wanted penny candy, it would cost 2 cents. One penny for the candy, and one penny for the 5% tax on the first penny. A penny doesn't have enough skin depth to support welfare.

Actually, I measured both phase and amplitude of the current at both ends of a toroidal inductor. It was measured at the base of a shortened vertical antenna, and also on the bench with the antenna replaced by lumped components having the same impedance as the antenna. The results were published in the October 2003 thread on this newsgroup.

I missed the part about why the billionaire gets a refund.\

It never works that way in the real world, Richard. How it works, and I'm from a retail family, is that you will get charged 2 cents for the penny candy. Except nothing costs a penny anymore, penny candy is at least 10 to 20 cents, so that is a moot argument.

And when you deal with all the combinations of price and tax, and how the retailer has to handle it, by law, the retailer loses money on average handling the tax for the state/local govt. In other words, the tax is 7%, but because of how the govt. makes the tax tables work, the retailer collects less than 7%, but is required to give the govt. exactly 7% plus a penny.

The business is almost always screwed, and the consumer is usually, not always like the seller, required to pick up the extra cost the govt. added.

Hi Bob, attempting to model a curved wire will possibly lead to
over-segmentation. It is also important to avoid junctions of dissimilar
wire diameters as it can lead to errors. The source wire should therefore
be the same diameter as the rest of the structure.

Tom,
I have no problem with most of what you have stated.
The last paragraph is where you actually address my question ie extra
thin material
relative to calculated skin depth for a particular frequency but then
you slide off and state that is another matter! The fact is that I am
refferring to the use of metallised mylar with antennas. Obviously the
metalised thickness could less than any "skin" thicknes.
So one has to decide I can compromise by adding more area to compensate
and by how much. I see this as possibly the most effective
change with respect to radiation since we now have forced more current
to the extreme outside surface but this is conjecture on my part.
The answer that is comming back at me is that the current
density is essentially the same but with no explanation
as to why the decay rate has changed since that which creates it has
not changed.
I find it difficult to accept that
the decay rate has changed
and intuatively I would have thought the surface current
would increase significantly.
All told I don't feel that I have
got anywhere in my quest other than forget skin depth
and just look at it as a volume problem as that is the way it is. Yes
there are what are called proximatry
effects but first we must have an understanding R.F. using a single
element alone.

Hello all

I've made a first attempt at installing an antenna. It's a 2 Slinky dipole strung across my roof. I chose the Slinky dipole because it promised to give good (if not excellent) results in a relatively short antenna. I strung it between two 2' wood standards at the top of the roof. The roof is about 25-30' from the ground. I used the twin feedline, which is about 18', and the insulators from a GSRV Mini antenna I bought. The twinline is connected with a balun to a 50' RG-8X cable that runs across the roof and down to my window. I've temporarily led it in through the window. The excess cable, probably about 20 feet or so, is loosely coiled between the inner and outer window.

The reception is great. I was picking up DX from Europe. However, I got no answers to any attempt to call out. I wasn't expecting DX for my very first QSO, but I was hoping for someone.

I think it may be because the feedline runs along the roof rather than hanging in free space. Could this be the case? The SWR was terrible; it took my automatic tuner a lot of work to get a match, but I was getting 1.5 or less on 80 and 40.

Thank you for any advice you can offer.

Actually, the entire antenna design is terrible. What is the SWR
on the coax at the balun? Steel is not a good conductor to use in
an antenna at RF frequencies.

Thank you for your response

I'm afraid I don't have a way of measuring the SWR at the coax.

Should I consider connecting the balun directly to the slinkys rather than
at the end of the twinline? Should the twinline be supported so that it is
not lying on the roof?

Or should I just dismantle it and go back to positioning the GSRV Mini.
That, at least, is a copper dipole.

Thanks again

Basil, VE3JEB

I won't presume to tell you what you "should" do. There are
too many unknowns in your system. You may need to spring for
an antenna analyzer, like the MFJ-259B. If it were me, I
would junk the slinky antenna. At least the half-sized
G5RV is known to work relatively well on 40m, 20m, 10m,
and 6m.

There's a conductive compound that reduces oxidation. It's
sold under various brand names. Oxiguard comes to mind
but that may be a toothpaste compound or some such. :-)

As Cecil said , it is hard to tell you what to do with the limiated information you have given. Nothing simple beats the good old dipole antenna. Problem is it is mostly a one band antenna. I have up an off center fed antenna and it seems to work fair for all the harmonic bands. The swr is a bit high on the WARC bands. It is about 130 feet long with a 4:1 balun in the center and fed with rg-8x coax.

Even with the antenna you have up you should be able to work something if the rig will load it. It may be that the internal tuner to the rig is not able to match the antenna and most of the power is not getting out of the rig. The inernal tuners are only good for about a 3:1 or less swr to the antenna on most rigs.
Cecil mentioned an expensive MFJ device. It is probably way too much over kill for most hams. One of the least expensive SWR meters will tell you if the antenna is anywhere in the ball park and which way you need to trim the antenna if you take several readings across the band.

Thank you, Ralph

I'm sorry if I am giving inadequate information. Besides the basic description of the antenna, I'm not sure what else to offer. I doubt it took anyone long to realize that I am a novice and have as much info on antennas as one learns for the Canadian basic exam, and and can glean from a borrowed copy of the ARRL Antenna Book.

The only additions I have are that on closer inspection, the balun is Van Gorden's (the manufacturer of the original antenna) Hi-Q Center Insulator. Also, I am using an external automatic tuner, a Z-11 Pro by LDG. It apparently tunes the antenna down to an SWR of <1.5, but doesn't have the means to give a more accurate figure. My FT-875 displays SWR, as a bar display, but when the tuner has done its job, the rig seems to display no SWR bars, which I take to mean the rig sees a 1:1 or close to it. Still, I guess that's no guarantee that the power is being used efficiently.

Anyway, thanks again for your help

The best, all round, all band, antenna is a high centre-fed dipole of
no particular length, fed with an open-wire feedline of no particular
length or impedance, all the way to the shack, used with a choke-balun
and an unbalanced tuner.

It is good down to the frequency at which the dipole is about
1/3-wavelength long.

Simplicity = efficiency.

Once tried you will never return to anything else.

An antenna tuner doesn't change the SWR between the tuner
and the antenna. If it's 100:1 before the tuner does its
thing, it is still 100:1 after the tuner does its thing.
The extra feedline losses are caused by that unchanging SWR.

Please allow me to share other thoughts on this subject in the hope
that someone can point to error that is contributing to my personal
problem Skin depth relates to decay or true resistance,as the current
penetrates
the conductor layers will form due to time involved
and will be seen as differing phase levels. The majority of this
decaying
energy is absorbed by the element and constitutes "true"
resistance similar to D.C. The energy layer at the very surface of an
element can react or change phase as quickly as the current changes
that is traveling along its surface and can immediatly
show a reaction by generating a field in its immediate vicinity which
one can call a radiation field A field created by the changed of
current flow at the surface where resistance can be close to zero and
can be seen as part of the resistance portrayed as "radiation"
resistance. But as
the current enters deeper into the conductor its phases changes during
the penetration time and changes more as it struggles back to the
conductor surface where often the phase of the surface current changes
before it can get back to the surface and help with the field formation
exercise
because in the meantime the surface current phase has changed again and
its energy carrying capablities become
totaly heat related
without contributing
to field generation.
Fortunately some layers of current flow are close enough to the surface
and a portion and provides a field at the surface albiet weaker than
the first generated line of field because of time change and decay or
heat loss.
Thus the radiation resistance of its particular travel will contribute
to the overall "radiation resistance" but it generated losses
which do not contribute to radiation. Continued on next posting

For a first attempt, it sounds like you've built a complicated affair:
slinkies, twinlead, balun, coax, tuner, etc. You might try the other
extreme, simple. A dipole of two straight wires cut to frequency, and
a length of coax to the rig. Make the antenna a little long, and use
your rig's swr meter to adjust the length down to resonance.

There is nothing in your post to indicate how long or short your
antenna is. Perhaps it is a well known design and I just haven't heard
of it in my limited experience.

You say how difficult the coax was to match with an ATU, that is a big
hint that the coax is operating at high VSWR. You say the SWR was
terrible, what does that mean, do you have the numbers? Coax operated
at high VSWR for significant length is quite lossy.

If the impedance presented to the tuner is extreme, you can expect
excessive losses there too.

The ambient noise on low HF bands is very high compared to the noise
floor in your receiver. An antenna system could be seriously lossy,
and yet still allow you to hear all signals above the noise (though at
reduced S meter deflection). Beware of depending on a simplified
receiver test to infer transmit performance.

Yep, though feedline losses are not usually so large as to preclude at least SOME QSO's on 80 and 40 unless that SWR is AT LEAST 50 (especially on 80m). Of course poor quality coax and twinlead that is touching metal can really increase those losses, even though they actually REDUCE the SWR that the tuner is seeing.

A slinky is such a poor antenna to begin with (basically a coil of iron), it's probably best to just feed it in the center with good quality 450 ohm line (which you then dress properly all the way to the tuner's balanced output--if the tuner has one or a balun located AT the tuner if it doesn't). Next best would be to feed it with decent COAX like LMR400 or better.

For example, my balcony whip gives an SWR of almost 6 on CW at 3652. I could lower this by adding a capacity rig at the stinger end of the hamstick, but I'm a bit too lazy to keep going out and taking it off and the thing is resonant on 3729 where our phone net meets. But it's still 88 percent as efficient as it is at resonance when tuned up on 3652 with my tuner, which can tune that SWR flat. (We won't talk about how inefficient an 8ft antenna actually is on these frequencies, but you get the point).

And that's using RG8X (Belden 9258). Better coax would improve that some. If the slinky actually has an SWR of 100, then 450 ohm ladder line would introduce additional loss, due to SWR of 2.04 db per 100 feet.

Moral of the story, when using inefficient antennas with weird impedances, then make sure you use good, low-loss feedline and keep it short as you can.

Continued
As can be seen the lossless reaction occures at a infitesimal depth
of the conductor where penetration is close to zero and the energy
transformation is close to being a maximum.
The reverse occurs
when a conductor
is in the way of the advancing field.
The action and reaction chain of events occur again
only this time it is the field that is creating current flow which then
creates both radiation by returning energy back to the immediate field
but not equal and opposite like a reflector would.
So ideally current
penetration of a conductor should
be curtailed either by having a lossless conductor
or by ensuring the surface layer constrains penetration of energy
enabling it to react in an energy conserving
manner. Yes overall resistance
will rise but resistance due to decay will be close to absent.
So the question is can aluminised mylar be used to advantage where skin
depth is more than the thickness
of the aluminum, tho I am quite sure the mylar carrier is going to
muddy up the waters.
Hopefully the above
possibly erronoius thoughts will help those who could help me by
allowing understanding of my dillema and question.
Regards
Art
Yes Roy ofcourse I am interested in the question why else would I post
and place myself in the inevitable firing
line that will arise from certain miscreants?

Ah, but how do you know you learned the RIGHT things? Or what you learned was true and correct?

The participants in the argument NEVER agreed on ANYTHING. So what can bystanders do?

I learned far more about people than I did about current through coils. Quite interesting nevertheless.

Reg, G4FGQ.

I tried learning something. I didn't get to read the whole thread so
may have missed the important part?

When the measurements of the coil were done on the bench it seems that
it was done with 50 ohms in and 50 ohms out. That hardly seems like it
would give the same information as when the coil was in actual use as
an antenna loading coil.

Rather than a 50 ohm load how about if a load was placed at the end of
the coil to simulate the antenna, a resistor and capacitor to take the
place of the antenna impedance and reactance. Then measure the current
in and out and the phase shift.

You're forgetting about the UPSTREAM data and interactive signals (QPSK
and/or QAM, from the cable modem or the set-top TV box). These will be
in the range of (probably) 15MHz to 42MHz. The max transmit level will
be typically 40dBmV (max around 56dBmV). The actual frequency used will
depend on the local area (segment).

The upstream levels are higher than the downstream (typically 10dBmV
analogue, 0dBmV QAM). However, where possible, the cable operator may be
avoiding the HF amateur frequencies, in order to minimise any problems
of ingress.

>There's some possibility, I suppose, of some leakage of noise from the

This is certainly a good idea 'just in case', and won't hurt any.

Just my two cents worth

For my first transmission aerial I made a three band trapped dipole of split figure 8 mains cable(80,40 and 20) and fed it with coax, and strung the centre about 25 foot in the air and falling to about 10 foot at the ends. This has enabled me to work Britain, Spain, Italy and the US with 40 odd watts SSB. SWR is not perfect and perhaps I should prune it a little. The hardest part was tuning the traps. I believe this design came from the arrl handbook.

I know that its not perfect and perhaps I should refine it, but for a starter aerial I have found it very good. Having said that there are things about it I want to experiment with.

One thing I have found invaluable is more experienced local hams who will help.

There are people much more knowledgeable about antennas here than me, but I am very happy with my home-brew antenna.

Reg,

If Basil measured the SWR at the ATU end of the RG8/X (either directly or effectively with the ATU in bypass configuration if that is possible), that would provide information that could be used to estimate whether losses in the RG8/X were reasonable, and if reasonable, how reasonable.

The RG8/X is probably the highest risk of serious loss in the antenna system.

For clarity, I am not at all interested in the VSWR indicated looking into the ATU unless the ATU is in the bypass configuration, in which case the measurement is a valid indicator of the VSWR on the RG8/X.

The line loss of 50' of RG8/X at 3.6MHz with a source end VSWR of 8:1 is around 1dB, and probably quite acceptable. Beyond a source end VSWR of 20:1, losses increase quickly to infinite loss at source end VSWR around 28:1. If the indicated reflected *power* at the ATU end of the coax is less than about 80%, or VSWR less than about 20, coax loss is probably manageable.

I think you are misusing the term "radiation resistance" in this exploration, but I think an important point in any understanding of skin effect is that currents of different depths have different phases, compared to the surface current. They lag it. They are the wire's memory of the previous cycle. In this respect, they remind me of the current in a pole shading winding of a shaded pole motor.

I tried to avoid that. Radiation resistance pertaines to that contained
in the radiation phenomina
exchange of energy which is of main interest to us.
This obviously is not the total resistance involved in the energy
exchange as heat does not generate
radiation. The word ":decay" aptly describes that.
Thanks for the comment,
anything helps at this point

Since the foundation of other's measurements was
the use of standing wave current phase to prove the
percentage of a wavelength occupied by a loading
coil is zero, my objective was simple: To prove
that the standing wave current, with its unchanging
phase, cannot be used to make a valid measurement
of the percentage of a wavelength occupied by a loading
coil.

I proved that using the standing wave current phase to
measure the percentage of a wavelength occupied by a
wire or a whip also yields an answer of zero. If the
coil plus the whip both occupy a percentage of a
wavelength equal to zero, all sorts of laws of physics
are violated. Not to mention a full length 1/2WL wire
dipole occupying a percentage of a wavelength equal
to zero.

Cecil,

I downloaded your EZNEC file, and I played around for a while with both the original and several variations.

There were no surprises for the fundamental frequency case. When I modeled a real bugcatcher coil, or at least as real as those on the GLA web site, the current at the top of the coil was 85% to 90% of the base current. I think it is more typical that a bugcatcher coil is at least 4 turns per inch rather than the 2 turns per inch in your example. I also attempted to model the coil tested by Tom, W8JI, and reported earlier in this thread. This coil pushes EZNEC both in terms of the number of segments and the short length of the segments, but in any case it appears that his coil when placed in your antenna model has higher current at the top than you reported.

I ignored the harmonic examples. Who ever said that a coil would be a lumped inductor when it is operated above its self resonant frequency? Even your new guru from Mount Olympus, Dr. Teslacoil, does not discuss such things.

In summary, the world of RF electrical phenomena is still intact. I don't believe I have anything more to add, and I plan to back to sleep.

The measurement problem is harder than it looks. Here's
a quote from "Field and Waves in Modern Radio", Ramo and
Whinnery, 2nd edition, page 227.

"Difficulties in applying these equations arise since
the current and charge distributions are not known, but
are determined by the field distributions which are
calculated from the retarded potentials which depend
upon current and charge distribution - a vicious circle!
The exact solution of this problem is usually of
prohibitive difficulty."

Hi

I was just digging around the garage and I found my old multi band trap vertical antenna LOL.. Anyway it covered 80m to 10m and I got it from Dick Smith back in the 80's that's a long time ago.. Dos anyone have a diagram for one of them I can not find mine but still looking for it.. Can any one help..

73's Regards,

Richard Miller

I tried 4 turns per inch. EZNEC didn't like it.

> I ignored the harmonic examples. Who ever said that a coil would be a
> lumped inductor when it is operated above its self resonant frequency?

Whoever said that a coil would be a lumped inductor at 60%
of its self resonant frequency? Did you say that?

Used at 5.89 MHz, self-resonant at 9.75 MHz, phase-reversing at
11.78 MHz. Sounds a lot like a slow wave transmission line to me.
5.89 is 60% of the self-resonant frequency. Dr. Corum says that
the lumped-circuit fails above a 15% value. 60% is far above 15%.

> In summary, the world of RF electrical phenomena is still intact.

Of course, and more than that, I took its side in the argument.

When I reported measuring no phase shift up and down a dipole,
Tom, W8JI, said my measurements were wrong. But EZNEC says
the same thing as I.

Oh, I forgot to ask you a technical question, Gene. Given that
at 11.78 MHz, the current at the bottom of the coil is 0.17 amps
and the current at the top is 2.0 amps, how do you explain those
values if the current is flowing up through the coil? The details
are at the bottom of the following web page.

Hi Reg

I note that you question my ability to know if I learned the Right Things.
How do we ever know?? I wrote that I learned a FEW things. Let me be the
judge about whats right for me.
I dont know if you wrote the question about my learning the Right thing to
impune my ability to sort out the Right from the NotRight, or you wrote to
imply that were some statements made in the thread that werent right.
I submit to you that if you find the need to show where any statement made
in the antenna group that isnt True and Correct, you can correct them
directly.
By my standards, all the posts in this thread were worthy of being read.
It is even possible that you learn something from these guys on the
antenna group when you take time to read and think.
Please dont stop trying to learn Reg, you are a great source of good
information and you can improve if you try.

Jerry

A bench test is fine. An inductor is an inductor.

The only problem with a bench test is simulating the load impedance presented by the antenna and of course strong local fields generated by the antenna are missing, but the actual error can be reasonably small.

However, inductors were measured in an actual antenna. I measured current, and Roy Lewallen measured phase and current.

I couldn't measure time delay or phase in my actual antenna because I was measuring a mobile antenna. There wasn't any way to measure phase without perturbing the system and rendering any data unreliable.

This long painful thread (it's been going on years now) started because K3BU claimed a loading inductor had most of the current in the first few turns. I made some measurements
and posted them at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

These measurements show exactly what anyone who understands loading coils would expect, that it is stray C in comparison to load impedance on the inductor that determines any current taper, and that for a reasonable sized inductor the taper is very small.

I wrote a description at:

http://www.w8ji.com/mobile_and_loaded_antenna.htm

I can't see anything in there that needs changed, based on what I've read here in this thread.

> Rather than a 50 ohm load how about if a load was placed at the end of
> the coil to simulate the antenna, a resistor and capacitor to take the
> place of the antenna impedance and reactance. Then measure the current
> in and out and the phase shift.

I've done that also.

You are absolutely correct Gary, it is possible to come very close with a lumped load on the inductor *except* of course the surroundings are

different.

The inductor test fixture I normally use is a large copper box made from blank double sided PC board sheets. It has vacuum caps (very high Q) and various detectors and probes.

I have to characterize large inductors on occasion as part of designing RF systems. It's less scary than turning on a 50kW PA and having things misbehave at full power, or building a phasing system or phasing/ATU combo that doesn't work.

way of thinking, how is that possible?
****
> A bench test is fine. An inductor is an inductor.

But the chosen valid model varies depending upon which inductor
it is. Dr. Corum says the model must be changed over at 15 degrees
of the self-resonant frequency. These are velocity inhibited slow-
wave helical coils that we are talking about.

And standing wave current is certainly not traveling wave
current. Remember what Gene Fuller said? Please read it again.

> Gene said about standing wave current:
>> Phase is gone. Kaput. Vanished. Cannot be recovered.
>> Never to be seen again. The only "phase" remaining is the
>> cos (kz) term, which is really an amplitude description,
>> not a phase.

How can one use a signal where the phase is gone to measure phase?

> However, inductors were measured in an actual antenna. I measured
> current, and Roy Lewallen measured phase and current.

You and Roy measured standing wave current the phase of which is
unchanging over the coil and whip and entire antenna. You should
have realized over the past week that those measurements were
meaningless. EZNEC shows the same thing. Kraus reports the same
thing.

ONE CANNOT USE THE PHASE OF STANDING WAVE CURRENT TO MEASURE THE
PART OF AN ANTENNA THAT A LOADING COIL REPLACES.

> ... and that for a
> reasonable sized inductor the taper is very small.

The present argument is not about taper, it is about how much of
a wavelength a loading coil occupies. One cannot measure that value
using standing wave current as you and Roy did. Roy reported
accurate phase measurements but standing wave current phase is

meaningless since it has unchanging phase.

> for my side of the argument. Thanks very much.

Cecil,

I am attaching a few of your quotes in this thread. Sorry to hear about your total loss of short term memory.

[Direct quotes from March 5-7]

Standing wave current is a net charge flow of zero. Standing wave current is DIFFERENT from traveling wave current. At any and every point, the standing wave current is NOT moving. Since it is not moving, there is NO net charge flow.

******

To tell the truth, standing waves are a product of the human mind. The forward and reflected waves couldn't care less about standing waves

Surely you understand that standing waves in a transmission line don't flow - they just stand there, which is why they are called "standing waves". Exactly the same principle applies to standing wave antennas.

The two traveling waves have to be analyzed separately and then superposed to obtain valid results. If you analyze net current without superposition, you are doing the same thing as superposing powers, which is a known no-no.

******

The currents that are doing the flowing are the underlying current components, the forward current and the reflected current and they are close to equal. Everything you say about a coil is true for the forward current and the reflected current. It is simply not true for the standing wave current which is just a conceptual construct and not a flowing phasor at all.

If you really want to accurately apply the principles you are asserting, you must treat the forward current and reflected current separately and

then superpose the results. Applying your above principle to standing
wave current is akin to superposing power and that's a no-no.

I have never seen such a wide-spread blind spot.

[end quotes]

Cecil,

Why is this an issue? Is there someone other than your strawman who has a problem with this concept? I don't recall anyone ever questioning such matters. Only in your imagination does anyone deny the existence of distributed, non-lumped components.

If there really is such a person, it might be better to address your query to him or to her.

I'm in a learning process here and using the scientific method to
correct my mistakes. Isn't that what rational people do?

> [Direct quotes from March 5-7]
> Standing wave current is a net charge flow of zero.

I was corrected on that one and already admitted my mistake. The
charges obviously migrate from end to end in the antenna.

> Surely you understand that standing waves in a transmission line don't
> flow - they just stand there, which is why they are called "standing
> waves". Exactly the same principle applies to standing wave antennas.

This means the same thing as your posting that phase is gone.
A phasor requires a rotating phasor to exhibit flow in the
real sense of the word. Standing wave current doesn't possess
a rotating phasor so it is not flowing in the normal sense of
current flow.

If you think standing wave current is flowing, how do you explain
0.17 amps at the bottom of the coil and 2.0 amps at the top?

http://www.qsl.net/w5dxp/current.htm bottom of page

> The two traveling waves have to be analyzed separately and then
> superposed to obtain valid results.

Don't see anything wrong with that. If one uses the standing wave
current phase to try to measure phase shift through a coil, one is
making a mistake as has been demonstrated here.

> The currents that are doing the flowing are the underlying current

You said it yourself, Gene, phase has disappeared from standing wave
current. Do you understand the implications of your statements?

You seem to be trying to have it both ways. 0.17 amps
is not equal to 2.0 amps. 0 degrees is not equal to
180 degrees. How are those values possible in a lumped
inductor?

There is more to contacting DX then trying different antennas. You say
you are picking up DX from Europe so you obviously have a setup that
receives reasonably. How efficient it is transmitting is a different
issue. Can you make local contacts in Canada and the USA?

I was just trying to contact CN2R in Morrocco on 80 meters. I could
hear him fine but he doesn't seem to hear me. Well I am running 100
watts with a trap dipole. He probably can't hear me. He is also
probably running a kilowatt and I know he has great antennas. Much of
the DX you will hear may be running 10 times the power you are and that
is why you hear them and they don't hear you. Don't worry about the
antenna too much until you make local contacts and work your way out to
greater distances.
Also, you may have to call for a long time to get through the pileup
calling the DX (which you may not hear). Try calling CQ DX yourself and

see if anyone comes back.

Both those sentences are false.

In a linear system like an antenna or transmission line, superposition applies. This means, among other things, that we can separately analyze the system's response to various components, and the sum of the results we get are the response to the sum of the excitation components. For example, we can split a current into two -- or more -- components, such as a forward traveling current wave and a reverse traveling current wave, with the actual current (or what Cecil calls "net" or "standing wave" current) at any point being the sum of the two. We can find the voltage across an inductor, for example, which results from the forward traveling current. Then we find the voltage across the inductor resulting from the reverse traveling current. Superposition tells us that the sum of those two voltages is what results from a current which is equal to the sum of the forward and reverse traveling current waves.

We must get exactly the same result, in this example the voltage across the inductor, if we find it by adding the separate voltages due individually to the two current components, or if we find it directly as a result of the total current. We don't have to separate the current into two components then superpose the results as Cecil claims -- we get exactly the same result either way because superposition holds. This has nothing to do with attempted superposition of powers or other properties which don't fit into the boundaries of linear quantities.

We're not restricted to splitting the current into a single forward and reverse wave, either. We can split it into many separate traveling waves, as well as any number of other combinations. As long as all the components add up to the actual total current, we'll get exactly the same result when we separately sum the responses to each individual component that we do when we simply look at the response to the total current.

If Cecil's analysis shows, or his theory requires, that the result be different when adding the responses to traveling current waves than it is by calculating the response directly from the total current, then the analysis or theory is wrong. Superposition requires that the two results be identical.

There is a phase shift through the coil for the individual
phasors. When the phasors are superposed, that phase shift
information disappears. That's what I meant by my statement.
The results are the same but information is lost.

Please see http://www.qsl.net/w5dxp/current.htm "Why the net
current is not constant through a loading coil" and take a look
at the phase of the net current. It is unchanging. Those phasors
are copied directly from "Optics" by Hecht.

What I was talking specifically about is the phase shift through
the coil so let's discuss that one limited technical subject.

The form of the forward traveling wave current is function(kz+wt)
The form of the reflected traveling wave current is function(kz-wt)
When we superpose those two waves we get the standing wave current.
The form of the standing wave current is function(kz)*function(wt)
A lot of information, including all phase information, has been lost
in that superposition process.

The standing wave current is obviously not like the traveling wave
currents because the equations are different. As Gene Fuller said
earlier, it has been stripped of all phase information by the
superposition process. You pointed out a couple of days ago that the
phase of the standing wave current is virtually constant from feedpoint
to the tip of the antenna while the phase of the traveling waves are
certainly not constant.

I have asked this technical question before and no one has answered
it. Given that the standing wave current would indicate a phase
shift of zero in 45 degrees of a wire antenna, what does that imply
for using the standing wave current to measure the number of degrees
of the antenna occupied by the loading coil?

If the standing wave current cannot determine the phase shift in
a wire, why does anyone think it can determine the phase shift
in a wire formed into a coil?

Kraus and EZNEC tell us that the standing wave phase shift is zero
from tip to tip in a 1/2WL thin-wire dipole. Why is it a surprise

that if we replace part of that antenna with a loading coil the standing wave phase shift doesn't change and is still zero? What useful information does knowing that provide?

Since the standing wave current phase is unchanging, how can it be used to determine how much of an antenna has been replaced by a loading coil?

You and Tom have used standing wave current for your measurements. Delays and phases cannot be measured using standing wave current because standing wave current doesn't contain any phase related information. As Gene said, it lost all phase information in the superposition. All we can gather from the standing wave current is that the forward current and reflected current phasors are rotating in opposite directions. The delay experienced by the traveling waves is hidden by the superposition process.

I refer to the diagram in the section entitled "What EZNEC Says About
Current Distribution Using Inductive Loading Stubs"

You use the diagram to assert that there is "not a lot of difference
between inductive loading stubs and loading coils" by comparing the
current distribution with another case.

You show graphically the current on each side of the stub. You do not
show the current in each wire of the stub or the sum of the currents
in the stub.

EZNEC calculates the currents in each wire of the stub? Aren't those
currents a relevant detail that you have omitted from the diagram.

Owen

I don't quite follow the theory on the web page, but what does it predict should happen if there were no antenna at all, and the inductor were connected to a simple series RC circuit instead of the whip?

I've taken the EZNEC model available there and modified it by replacing the whip with a wire to ground from the top of the coil (http://eznec.com/misc/test316_modified.EZ). I added a lumped impedance in that wire to represent the impedance of the vertical wire I deleted(*). The feedpoint impedance is the same as for the original model, and the currents at the top and bottom of the inductor are almost exactly the same as for the original model. Can the traveling wave analysis be used to explain the inductor currents in this model? Is traveling wave analysis necessary to explain them?

(*) The impedance inserted in the new wire isn't equal to the impedance of the top wire driven against ground. The reason is that the new wire to ground does radiate some, does have significant impedance itself, and does interact with the inductor. The modified system, however, is quite obviously very different in radiating properties from the original, and isn't too different from a lumped RC load.

Yes it is possible. There is no difference between doing things as
lumped components or standing wave models.

The only disagreement is you seem to claim some very odd things about
current not flowing, unless in the course of 400 posts you have
corrected that.

This entire thread reminds me of the Fractenna threads of years ago.

Owen and Basil,

The slinky dipole comes from the misplaced notion that packing a few hundred feet of wire in a ten or twenty foot area makes an antenna a few hundred feet long.

They totally miss the point of why an antenna radiates and how the steel spiral affects the efficiency. There isn't any attempt to make the antenna resoant either!

Overall it is a terrible system, unless you just happen through luck to use it where the antenna has a low-order resonance and current maximum at the feedpoint.

You could probably trim the slinky and make it work on a few bands where it would be OK.

If you have enough room, just put up a dipole. Watch out for these gimmick antennas. There isn't any magic bullet with antennas.

Notice that the current into the grounded wire at the bottom of the coil is about 1 amp, and the current going into ground at the grounded end of the added wire is about 0.56 amp. So where is the extra current for the coil bottom wire coming from? The answer is displacement current from the coil. That is, the coil is capacitively coupled to ground, and this causes displacement current from the coil to ground. The effect is greatest at the end of the coil which is farthest from the source. A decent model of the coil is an L network, with a series L, and a shunt C to ground from the far end. This is all that's necessary to explain the drop in current from the bottom to the top; no current waves, standing or traveling, no transmission line analysis are required.

If you're not convinced, try this. Change the ground type to free space. Then connect the bottoms of the two formerly grounded wires together with another wire. You'll see that the current at the top of the coil is now very nearly the same as at the bottom. We haven't changed any waves, antenna lengths, or anything else related to antennas or waves. All we've done is to eliminate the other side of the capacitor -- we've removed the C in the equivalent lumped L network.

A simple lumped component model explains the difference between grounded and free space models just fine. How well does the traveling wave theory do at it?

The currents in stubs cannot be displayed very well at full size in
EZNEC just as the currents in coils cannot be displayed very well.
Maybe an enlarged view would show it. I will try to do that.

> EZNEC calculates the currents in each wire of the stub? Aren't those

Remember the present discussion is about the ability to use standing
wave current phase to measure the electrical length of a wire or a
coil. I have run the currents that you mention. The phase of the current
is almost constant through the stubs. The phase of the current is
almost constant through the coils. Would you like to see a list
of the current at points through the stub Vs the current at points
through the coil?

In this new configuration, the traveling wave current
encounters a short-circuit to ground instead of the
open-circuit in a normal antenna. And that forward current
is reflected by that short circuit. In the shorted case
its phase doesn't change so the forward and reflected
currents add instead of subtrace. But their phasors are
still rotating in opposite directions. Please note that
the phase shift in the standing wave current is almost
zero throughout the system, i.e. standing wave phase
information has still been lost. We still don't know
the electrical length of the coil for the same reasons
we didn't know it before. Below 'func' stands for
'function of'.

The standing wave current reported by EZNEC is of the
form: func(kz)*func(wt) = fun(kz+wt) + func(kz-wt)

Is there any way in EZNEC to subtract out the func(kz-wt)
reflected term and leave just the forward term?

Please explain how 0.17 amps can be on the source side of a
lumped inductor while 2.0 amps exists at the top of the
inductor.

> be identical.

Superposition does not require that all information be preserved
through the superposition process. Here's an example:

Two people are across the room from each other with a coax cable running
between them. They each have two identical PSK modems but only one coax.
When they use one modem pair, any information one sends is received 100%
by the other. When they use the other modem pair, any information one
sends is received 100% by the other. When they superpose the signals
over the single coax line, all phase information is lost. The superposition
results are the same but all phase information is lost in the process.
The rules of superposition do not apply to the phase information content.
The phase information is lost in the process of superposition.

In like manner, the rules of superposition do not apply to the ability
of a standing wave to detect phase shift. The phase information is
lost in the process of superposition. One cannot use standing wave
current phase to measure the electrical length of a wire or a coil.

A 75m wire dipole is known to be close to 90 degrees long from the
feedpoint to the tip. EZNEC says the current changes phase by 2.5
degrees. How can current change phase by only 2.5 degrees in an
antenna wire known to be 90 degrees long?

Since EZNEC's standing wave current cannot detect a phase shift in
90 degrees of wire, why should it detect a phase shift in a coil?
If standing wave current measurements cannot detect a phase shift
in 90 degrees of wire, why should anyone's measurements detect a
phase shift in a coil?

Hello

I'm sorry, though I tried to word that idea carefully, I left room for confusion. I wasn't trying to work DX, I only meant that the antenna received a clear signal from distant stations. I know that this is entirely due to the sensitivity and selectivity of my receiver, and does not reflect the ability to transmit to that distance. I had no expectation of getting out to the rest of the world. I'd have been happy to talk to someone 3 miles from me, for a first QSO.

Thank you for your ideas, though.

Pirate radio's hip-hop tunes finding way to pilots' ears

These days, pilots at Miami International Airport are hearing something unexpected in their headphones: hip-hop from a pirate radio station.
BY DAVID OVALLE
dovalle@MiamiHerald.com

It began with airline pilots reporting hip-hop songs playing on two frequencies from a station calling itself Da Streetz.

Authorities pinpointed the source of the transmission: a stucco-and-brick, two-story warehouse in Opa-locka. Joseph Zeller, a state agent, discovered a large radio antenna mounted on a tower next to the building.

Armed with a search warrant, he confiscated three computers, a monitor, a mixing board, a stereo compressor, a microphone, a two-deck CD player, a telephone, a DSL modem, two stereo speakers, three gray three-ring binders and 10 cases filled with CDs.

But no radio transmitter. And no disc jockey.

''No arrests. This is still an open case,'' said Paige Patterson-Hughes, a Florida Department of Law Enforcement spokeswoman.

Meanwhile, Da Streetz remains on the air.

The music from the pirate radio station has been so troublesome over the last month that a federal engineer who specializes in frequency transmissions has arrived in Miami to help investigators locate the signal.

''It's intermittent. Not all day, every day,'' said Kathleen Bergen, a spokeswoman for the Federal Aviation Administration. ``But clear communication between air control and the pilots is a critical part of flying.''

Helping in the investigation: the Federal Communications Commission and the Florida Department of Law Enforcement.

It is believed to be the first such case worked by state agents in South Florida since a new law gave law enforcement broader authority to go after illegal radio stations.

It's unclear if agents have a suspect or how long the station has operated from the building. The owner of the warehouse had no idea the building was being used as an illegal station, authorities said.

With its flat terrain, South Florida has long been described as the pirate radio capital of the United States.

On any given day, between nine and 20 illegal stations are playing in South Florida, according to the Florida Association of Broadcasters. Some air around the clock; many switch frequencies and locations often.

''They get a kick out of it. They laugh at everybody,'' said C. Patrick Roberts, the organization's president.

With readily available technology and radio mega-companies that critics say have limited playlists, unlicensed radio stations have proliferated in recent years.

Supporters contend the stations provide niche programming -- often geared toward ethnic groups -- not found on overcommercialized radio stations.

The FAA says it has launched 30 similar investigations into pirate stations interfering with airport transmissions during the past decade. They now have more help from the state.

A Florida anti-piracy law went into effect last summer, making interfering with signals from licensed public or commercial stations, or broadcasting without a license, a third-degree felony.

That gave FDLE the power to aggressively go after pirate radio stations. Since then, agents have shut down about five illegal radio stations.

So far, they have arrested at least two men in South Florida.

Last year, agents shut down Vibez, a popular Caribbean station that had operated quite openly.

The ARRL Antenna Handbook starts at the very beginning and goes as far as you would like for ham radio designs. If you become so enthralled with antennas that you want to go into it professionally, there are other books but for us hams. that one will do.

Roy Lewallen wrote:
> -- we get
> exactly the same result either way because superposition holds.

Thinking that the result is the same and that nothing gets
lost during superpositon is a misconception. Consider the
following.

PSK modem A--------------------------------------PSK modem B

When a single signal flows from A to B, perfect information
transfer occurs. When a single signal flows from B to A,
perfect information transfer occurs. Now superpose the
two information streams. ZERO information transfer occurs.
Superposition is not magic and the result is not the same.

The superposition of forward and reflected currents cause
100% loss of phase information in the standing wave current
phase measurement. It is analogous to the problem above.

A standing wave current cannot be used to determine the
delay through a coil.

Or even words that explain that the diagram is incomplete, that there
are currents flowing in the stub wires, and that they don't balance
each other so they participate in the antenna's total current moment.

The currents in the stubs is an explanation for the difference in the
currents in the main radiator at each side of the stub connection.

Is it fair to say that though the diagram may resemble the first
diagram on the page, to some extent, the reason they are similar is
that the second one is incomplete.

>of the current at points through the stub Vs the current at points
>through the coil?

No thanks, I didn't ask the question without creating a model and inspecting the currents.

The phase of the currents is only one dimension. Though the phase of the current in adjacent segments in all wires (including the stubs) is commonly similar (except where a phase reversal occurs), in general, the magnitude and phase of paired stub segments that effectively form a transmission line section are not equal in magnitude and phase.

My point is really about whether the subject diagram supports your argument, especially if it is incomplete and if it misrepresents the scenario.

hi

i am pondering this again after thinking the odds of being about to put a beam up are slim

currently i have a nice dipole CF horiz via a topside sgc , i am happy w/it

i think i might be able to get a verticle (all bander) up there but then i wonder

overall if it would really pay from just a performance point of view

the reviews i see i personally average as some signals would prob come in bettter on one and some signals the other 'depending'

but i guess i can't quantify if at the end of the day i'd say wow really glad i had that vert or if perhaps having a 2nd antenna would really net me only a marginal end of year bunch of extra qso's

perhaps a unrelated question #2

given the building master tv antenna is close by, would one guess that a verticle or a small triband beam would give off more tvi??

assume both would be slightly higher than the tv ant but close proximity

thanks

I am back after loooong absence here and see more misinformation coming from Tom, W8JI.

I claimed that current in the antenna coil is NOT CONSTANT (or near) as he claimed.
The case was of electrical quarter wave vertical radiator (as loaded mobile antenna) and that the current is distributed, varying across the coil as I have experienced, W9UCW has measured and Cecil has explained.
The refresher is at
http://www.k3bu.us/loadingcoils.htm

The thread is "painful" because some people try to subvert the reality and keep clinging to wrong "reality" and some try to set the record straight..
This misinformation keeps being perpetuated in literature and it even crept into the latest ON4UN 4th edition of Low Band DXing (see page 9-33).

The significance of properly realizing the current distribution in the loading coil is in how the modeling programs treat the phenomena and major screw-up will show up in multi element loaded antenna systems, where error will multiply and give false results.
There are few more statements slightly out of true on W8JI pages, but would have to be left for later time.

I apologize for being away from this NG, my AOL provider dumped NG and I am slowly dumping AOL and will migrate to optonline.net and back to NG. Also business and other QRM keeps me away, but I hope is that "tings" will improve.

********** REPLY SEPARATOR **********

For a couple of years I had a 40 meter half-wave dipole and a 40 meter ground plane with elevated radials. Both were at about the same height and had full size elements (no loading coils). I'd say about 95% of the time the performance was nearly identical between the two, but there were times when one would outperform the other, but not by much.

If you are in an environment with high man made noise, you will find the horizontal dipole is quieter, but otherwise I would just put up which ever is easier mechanically, or ideally, put up both.

Yuri,

Why don't you explain in a few words how you think the loading coil
works?

Also, why do you think a mobile antenna is "90 degrees long" when it
has a loading coil?

The loading coil, if well-designed and of compact size, doesn't have to
have any significant current taper. The exception would be if the
antenna above the coil has small capacitance compared to distributed
capacitance from the coil to space or to ground.

Do you still disagree with this?

The phase shift through the stub is the same as through the coil is
the same as through the wire. It is simply zero according to the
standing wave current phase which is incapable of measuring phase.

Reg,

The type of antenna you describe is very useful and popular.

However, your assertion is much too sweeping as a generalization.
In no particular order, here are some caveats:
1. The qualifier "best" is largely meaningless, absent an agreed
set of weighted criteria for "goodness." (How important is:
size? weight? cost? visual profile? bandwidth? instant QSY?
gain? pattern? low-band performance vs. high-band performance?
power-handling capacity? need for tuner? etc., etc., etc.)
2. A good case can be made that choosing the "right" length is
"better" than a random length, within this type.
3. An excellent case can be made that center-fed is NOT always
the "best" option, within this type.
4. I'll let the fans of this antenna type chime in with why they
prefer balanced tuners and/or tuned feeders to the use of an
unbalanced tuner... if they want to. (I use more tailored antennas,
and don't need a tuner of any kind, most of the time.)

Only one out of a dozen tests run by W8JI and W7EL showed the
currents to be equal. All the other tests showed the currents to be
unequal.

> The significance of properly realizing the current distribution in the
> loading coil is in how the modeling programs treat the phenomena and major

The helix option in EZNEC supports the notion that the currents
are hardly ever equal. If a coil is installed at a standing wave current
maximum or minimum the currents can be equal. If the coil is installed
at a point where the slope of the current is maximum, the difference
in the currents at each end will be maximum. That's pretty simple physics.
The currents at each end of a coil in a standing wave environment depends
upon where it is installed.

I provided an example where the current "into" the bottom of the coil
was 0.17 amps and the current "out of" the top of the coil was 2.0 amps.
W8JI said the lumped-circuit inductance could explain that so I asked
him to explain it to all of us. So far, no response.

Wonder how a model that assumes faster than light propagation of waves
and absolutely equal current magnitude and phase is going to explain a
1.8 amp difference and a phase shift of 180 degrees?

The current taper depends upon where the coil is installed in
the standing wave environment. There is no doubt that the coil
distorts the current away from the ideal thin-wire dipole case.
But that coil does have to have a significant delay, in the tens
of degrees according to Dr. Corum. Since you and Roy mistakenly
used standing wave current phase to try to measure the delay
through a coil, the following posting resulted:

> Gene Fuller, W4SZ wrote:

Gene is 100% correct and we all should be grateful for that posting.

Neither you nor Roy have ever made a valid measurement of the
delay through a coil. It is admittedly a difficult measurement
to make directly. Ramo and Whinnery say it "is usually of
prohibitive difficulty".

For anyone who is foolish enough to believe Cecil when he says that
all phase information is lost when two oppositely traveling waves create
a standing wave, consider the following, adapted from Georg Joos book
Theoretical Physics:
consider two traveling waves going in opposite
directions represented mathematically by Ae^i(wt-kx) + Ae^i(wt+kx+d)
where A is the same amplitude for both waves, i is the square root
of -1, k is 2*pi/wavelength, w is the radian frequency, t is time,
x is distance, and d is the phase difference between the two waves.
This is just another way of writing 2Acos(kx+d/2)(e^i(wt+d/2). Notice
that the part cos(kx+d/2) still contains the phase information?
If Cecil were any kind of experimentalist he could easily tease the
phase information out of any standing wave on his antenna system.

Roy wrote, "... That is, the coil is capacitively coupled to ground,
and this
causes displacement current from the coil to ground."

In fact, if there were no such current -- if there were no capacitance from the coil to the world outside the coil -- then the time delay through the coil, calculated from tau = sqrt(L*C), would be zero. It is exactly this current that allows there to be a transmission-line behaviour and a corresponding time delay.

That's not to say, however, that a physically very small loading coil with practically no capacitance to ground would not work as a loading coil. It just wouldn't have a transmission line behaviour worth mentioning.

It is also exactly this displacement current from a large coil that allows the current at one end of the coil to be substantially different from the current at the other end.

Cheers,
Tom

Thanks Tom and others,

I've been trying to tell Yuri (and others) that for three years now.

The current reduction at the antenna end of a loading coil is actually dependent on the ratio of the termination impedance to the distributed capacitance (to the outside world) of the loading inductor.

One extreme would be something like a Tesla coil or helical whip, where the open end is open with virtually all capacitance distributed. The other extreme is an antenna with a reasonable amount of antenna capacitance above the inductor and a reasonably compact inductor.

I think what everyone has forgotten is a large amount of current taper in a loading coil of a short monopole, while possible, is a good indicator of a very poor antenna design.

I think it's a shame that useful things to learn are buried in all the noise.

Another product that works very well is Lawson 59933 Copper Anti-Seize
Anti-Corrosion Compound
http://webapp.lawsonproducts.com/website/showItem?itemNum=59933
This is the same product that comes with a Butternut vertical antenna. It
consists of a synthetic grease base, copper, thickener, and rust inhibitor.
It can withstand temperature ranges from -65&#65533;F to 1800&#65533;F, which should be
adequate for most ham applications.

I have previously teased that information from that equation.
Perhaps you forgot. It's how to determine the exact phase
shift along a thin-wire 1/2WL dipole. I showed how to do that
days/weeks/years ago. It's the *phase* of the standing wave
current that does not yield any phase information. I have been
very careful with that caveat in my statements.

cos(kx+d/2) indeed does still contain the phase information.
If you will re-read my postings, you will see that I said
the *PHASE* term of the reflected current doesn't contain any
phase information. FYI, that's the e^i(wt+d/2) term and that
part is what Roy used to make his phase measurements which
has been my objection for years. It's all archived on Google.

It is I, not Roy or Tom, who used the phase information in
cos(kx+d/2) to determine phase. When the term containing
the phase information is actually used, the delay through
the coil is shown to be in the tens of degrees.

In the 1/2WL thin-wire dipole, the phase shift between two
points is arc-cos(amplitude1) - arc-cos(amplitude2). The
only phase information is, as you and Gene Fuller rightly
assert, in the amplitude of the standing wave current, NOT
in the phase of the standing wave current that Roy measured.

If the e^i(wt+d/2) term is used, as Roy and Tom have done,
it suffers from the absence of any phase information at all.

Gene Fuller said it all days ago:
> Gene Fuller, W4SZ wrote:
>> In a standing wave antenna problem, such as the one you describe, there is no
>> remaining phase information. Any specific phase characteristics of the traveling
>> waves died out when the startup transients died out.
>> Phase is gone. Kaput. Vanished. Cannot be recovered. Never to be seen again.

i.e. there's no remaining phase information in e^i(wt+d/2) term.

>> The only "phase" remaining is the cos (kz) term, which is really an amplitude
>> description, not a phase.

i.e. there is phase information in the cos(k+d/2) term, but
that's not the part of the wave that Roy and Tom were using
to determine delay through the coil. I have been hoping someone
would jump in who understood the math.

To summarize: cos(kx+d/2) is proportional to the *amplitude* of
the standing wave current. When I used the amplitude of the
standing wave current to estimate the phase, the gurus
objected.

e^i(wt+d/2) is proportional to the phase of the standing wave
current and, ironically contains no phase information, just as
Gene asserted. Yet, this is what Roy chose to measure in trying
to determine the phase shift through a coil and that's the entire
problem with his measurements. He was expecting to measure zero
phase shift and he did because there was no phase shift information
available from his measurement of the e^i(wt+d/2) term.

I told Roy a long time ago, in general, how to calculate the phase
shift from the cos(kx+d/2 amplitude term but he replied with
"gobbledygook" or some such.

While zero current taper in a loading coil is a good indicator
of a confused engineer, unless of course, there's a current
maximum inside the coil or a very large top hat. The current
taper depends upon where the coil is installed in the standing
wave antenna system. Some positions can result in current flowing
into both ends of the coil at the same time, just like a transmission
line. But the delay through an HF loading coil is *NEVER* 3 nS.

Say Tom, you were going to explain to us how the lumped-circuit
inductor theory handles a coil with 0.17 amps at zero degrees
at the bottom of the coil and 2.0 amps at 180 degrees at the
top. We are still waiting.

Yes, it can be recovered and I showed how years ago. Roy and Tom rejected that approach and instead reverted to measuring the phase of the standing wave current which is known to contain zero phase information. Go figure.

Seriously, I showed those two how to calculate the phase shift in a 1/2WL thin-wire dipole using an arc-cos function. They responded with a personal attack. It's all on Google.

If you will check my past postings on Google, you will find me saying, if the current at the base of the coil is one amp, we can estimate the phase shift through the coil by arc-cos(It) where It is the current out of the top of the coil. That is admittedly a very rough estimate since the coil distorts the current away from a perfect cosine envelope but it is closer than measuring the phase of a signal whose phase is known to be unchanging.

Tom.
You tell that to the RF ammeters installed on the vertical, W9UCW's pictures on my page!
You can mumbo-jumbo all the theory, you can dream of, but reality shows that in the say, quarter wave vertical, with loading coil the current at both ends of the coil is different. Cecil explained the various situation depending where the coil is placed within the radiator and at overall antenna curve.

Try this test, no meters necessary (perhaps the aquarium strip thermometer): Take your 80m Hustler antenna with Hustler loading coil and whip. At the resonant frequency put about 600 Watts to it for a while. Stop transmitting and go feel (or read the temperature on the strips) the coil, bottom end and the top end. Same temperature? Temperature is proportional to the current flow (same diameter wire) - warmer end - more current.

Then test two: Keep the RF flowing until heat shrink tubing on the coil starts melting. Where does it melt first? Bottom of the coil or nicely uniformly as you claim it should?

Then answer Cecil question about his demonstration of different currents at the ends!
The rest is on my web page as I mentioned, with pictures.

Tom, the math equations that you posted supports Gene's assertions 100%.
They are essentially identical to the same equations that Gene posted.
Many thanks to both of you guys for posting the technical facts.

Yes. And this, not the C across the coil, is what should be used for transmission line formulas when treating an inductor as a transmission line. When the ground was removed and replaced by a wire, the transmission line properties of the coil changed dramatically, while the C across the coil didn't change significantly.

> allows the current at one end of the coil to be substantially different
> from the current at the other end.

Yes again, with one slight modification. You'll note from the EZNEC models that the current actually increases some as you go up from the bottom of the inductor. This is the effect noted by King which is due to imperfect coupling between turns. It results in currents at both ends being less than at the center.

A transmission line can be represented by a series of L networks with series L and shunt C. You can achieve any desired accuracy by breaking the total L and C into enough L network sections. The requirement for validity is that the length of line represented by each section must be very small relative to a wavelength. For the example coil, a single section is entirely adequate at the 5.89 MHz frequency of analysis. However, at some higher frequency this model won't be adequate, and either more L sections or a distributed model is necessary. If the reasons for this aren't obvious, many texts cover it quite well. No special "traveling wave" analysis is required.

I spent several years of my career designing very high speed TDR and sampling circuits, which involved a great deal of modeling. At the tens of GHz equivalent bandwidths of the circuitry, even very small

structures such as chip capacitors and short connecting runs often had to be treated as transmission lines. One of the skills important to building an accurate model which would run in a reasonable amount of time, particularly on the much slower machines being used in the earlier part of that period, is determining when a lumped L, pi, or tee model is adequate and when a full-blown transmission line model has to be used(*). My models were used in the development of quite a number of circuits that were successfully produced in large numbers.

(*) One of the characteristics of the SPICE programs at the time was that the time step was never longer than the delay of the shortest transmission line in the model. So if you willy-nilly modeled everything as a transmission line, you'd end up with an excruciatingly short time step and consequently unnecessarily long calculation time.

Cecil,

You keep trying to drag something from a self-resonant helice into a
loading coil discussion.

The two are nearly at opposite extremes in behavior, but even at that
the self-resonant helice can be analyzed with standar L/C analysis.

It's just another way to analyze things, and it's just one way of doing
it.

1.) I can build an antenna that has greatly uneven currents at the ends
of the loading coil, but the antenna rea above the inductor is wasted
and the system will be less efficient than a properly designed system.

2.) The meters are large and have a good deal of self-capacitance
compared to the capacitance at the point where they are connected, and
are directly connected to the antenna. Bad idea to base a whole concept
of how an antenna works on something like that.

> You can mumbo-jumbo all the theory, you can dream of, but reality shows that
> in the say, quarter wave vertical, with loading coil the current at both

It can be different, but in a well designed system it is essentially
the same. The only difference is caused by displacement currents, and
that is a result of stray capacitance. Wind a good coil that has low
self-C to the outside world compared to the antenna hanging above the
coil, and the problem of large uneven current goes away.

>Cecil explained the various situation
> depending where the coil is placed within the radiator and at overall

I doubt that. If he explained it in those terms he was missing some
important points.

Are you saying thermal effects have no bearing?

It's getting pretty dangerous to write a theory based only on a Hustler
mobile coil with almost no stinger above the coil. One of the reasons
the Hustler works so poorly is the distributed capacitance in the coil
is large compared to the tiny stinger above the coil.

The Hustler has narrow bandwidth and poor efficiency because of the
coil design.

> Then test two: Keep the RF flowing until heat shrink tubing on the coil

I never claimed uniformly in ALL coils. I set boundaries as to the conditions. I can replace that Hustler coil with another coil and ruin your theory about standing waves and missing antenna degrees.

> in bettter on one and some signals the other 'depending'

And HOW!
I've been running some experiments comparing the two, and frankly have been having some problems simplifying the experiment enough to make good sense and be valid at the same time.

Some times the vertical works better, and sometimes the horizontal works better. I'm having a heck of a time correlating exactly *why and when* (I'm not the only one - some Dutch amateurs got some surprising results when they tried to decipher what would be the best antenna to use in the PA contest. Some signals predicted to come in Groundwave were coming in Skywave, and vice versa - this was covered in a recent QST)

What I have seen from my experiments has led me to believe that the answer to "dipole vs Vertical is an emphatic, no question about it one answer only - YES!

You want both antennas if you can do it. Anyone who declares one or the other the winner is simply wrong.

Yea Tom, it all started with ALL coils, it is MY theory and you can ruin MY theory. Riiiight! It's getting pathetic. Yea, meters are too big, Hustler is crapy, Cecil is wrong, and you never claimed uniformly in all coils, just those that you have. Reality is wrong, your "theory" is right! Rrrrright!!! But what a coincidence that what W9UCW measured, jives with what Cecil calculated. Hmmm!

ANSWER Cecil's question about his modeled example. I guess when someone is stuck on something and dunt gitit, its tough!
I am just waiting how you will come around, dancing around in mumbo-jumbo circles and then will become guru on how current IS different in the loading coils. Happened in the past, will happen again. You are WRONG, reality proves it, regardless of your detours.

BTW, what engineering degree, from what university do you have or PE that gives you right to put labels like "JI Engineering" on your products?

I have a all band trap vertical and an all band linear loaded dipole.
Some days one is better than the other. It depends on propagation.
Often the verticle is stronger but the contact is easier to make on the
dipole because it is quieter. I would put both up if you have the room.

Message-ID: <3DqTf.62056$Dh.37069@dukeread04>
Source record: 62773

I'm installing 802.11b/g in my IBM ThinkPad T23. I've done quite
a bit of research and got a 250mw WiFi internal (mini PCI) card,
2 micro coax (1.37mm OD) antenna leads and I'm building two
antennas but I'm stumped on how to connect the antennas to the
laptop.

Ideally the connectors should be inline, like a headphone extension
cable. The connectors will be secured to the rear of the LCD display
in a way so that they point up when the display is open yet the antennas
can be removed when I close the screen.

Should I just use the 2 leftover Elecraft BNC chassis mounts I have?
Anyone have a better (smaller) choice? What about RCA or 3/32"
headphone plugs? Would they present too much of an impedance
bump at 5.1ghz?

Hi Ken

Yes stay away from RCA and headphone plugs, for exactly the reason you mentioned.

I'd recommend SMA plugs and sockets, They are in pretty standard use up to about 12GHz. Make sure you terminate them properly or have some cables made up.

I'd also be careful using that thin coax over any kind of distance. The losses will really mount up!

Cheers Bob

Thanks for the tips, Bob. I was worried about losses but I downloaded the factory data sheet for this coax - for a 500mm run, I'm looking at a loss of 0.94db @ 2.4ghz and 1.53db @ 5.1ghz. I tried finding the internal connector (U.FL type) but gave up when I saw DigiKey selling a 1000mm cable with U.FL connectors installed on both ends. I cut the cable in half. The cable looks like good stuff - VERY tiny but well built. $10....

I'll look into SMA connectors - does anyone know if they make a push on variant?

Tom's statement doesn't need modification, it's correct as written.
Imperfect coupling between turns causes current which is different at
the ends than in the middle. Tom said, correctly, that displacement
current is the cause of the currents at the ends being different from
each other.

Tom, W8JI wrote:
"What you are missing is the flux inside the coil links all the turns at light speed. When it does that, current appears at nearly the same instant of time (light speed over the spatial distance of the inductor) in all areas that are linked by flux."

Are any famous authors protagonists of that theory?

One author, Bill Orr, W6SAI writes in the 22nd edition of "Radio Handbook" on page 5.11:
"Spaced closely around the beam (in a TWT) is a circuit, in this case a helix of tightly wound wire, capable of propagating a slow wave. The r-f energy travels along the wire at the velocity of light but, because of the helical path, the energy progresses along the length of the tube at a considerably lower velocity that is determined by the pitch of the helix.

Maybe Varian has a paper on this (just my speculation).

Best regards, Richard Harrison, KB5WZI

OK, I have a new 2 meter j-pole antenna installed in my 3rd floor attic. I have 50 feet of LMR240 coax running to the basement. I measure SWR at the following frequencies on simplex.

144.2 2.5
145.2 2.4
146.2 2.3
147.2 1.9
147.9 1.7

Can I conclude that the antenna is electrically short for the 2 meter band?

Thanks for any insight, jimbo

Moral: The self-resonant frequency of a loading-coil needs to
be measured in the mobile antenna system, no on the bench.

> Yes again, with one slight modification. You'll note from the EZNEC

It results in a deviation away from the perfect cosine envelope
exhibited by a 1/2WL thin-wire dipole. In any case, the delay
through a 75m bugcatcher coil is tens of degrees, not 3 nS.

> If the
> reasons for this aren't obvious, many texts cover it quite well. No
> special "traveling wave" analysis is required.

The self-resonant frequency of that modeled coil is around 9 MHz.
Since the coil is 90 degrees at 9 MHz, it would be ~59 degrees
at 5.9 MHz. Dr. Corum suggests a 15 degree limit at which the
lumped-circuit model needs to be abandoned in favor of the
distributed-network model or Maxwell's equations.

> You keep trying to drag something from a self-resonant helice into a
> loading coil discussion.

My 75m bugcatcher coil is self-resonant around 6.7 MHz so it
meets the minimum requirement for a Tesla coil at 6.7 MHz.
4 MHz is 60% of the Tesla coil self-resonant frequency. The
coil is known to possess a 90 degree delay at 6.7 MHz. That
would make the delay ~60 degrees at 4 MHz. Dr. Corum suggests
a 15 degree limit for the lumped-circuit model.

> The two are nearly at opposite extremes in behavior, but even at that
> the self-resonant helice can be analyzed with standar L/C analysis.

Unfortunately, that's not true. One cannot assume the
presuppositions of one's model without proof. The "standar L/C
analysis " assumes the delay through a coil is zero, i.e.
faster than light. The delay through a self-resonant coil
is known to be 90 degrees. That "standar L/C" model is
invalid at the self-resonant frequency where the coil
is acting like a 1/4WL open-circuit transmission line
stub.

Take your 1/4WL electrical antenna and put another 1/4WL bottom
section beneath it. The current "flowing" into the bottom of
the coil will be higher than the current "flowing" out of the
top of the coil. Please explain that.

I did some tests a couple of years ago on 10 meters between vertical and horizontal on an 1800 mile path. It seems that there is quite a bit of rotation in polarity of the signal from minute to minute. I tried right and left hand circular to confirm that it was rotation.

In "Fields and Waves in Modern Radio", Ramo and Whinnery, 2nd edition, there is a section titled: "9-16 The Idealized Helix and Other Slow-Wave Structures". Quoting: "A rough picture would convince one that the wave should follow the *wire* with about the velocity of light, ..."

From the IEEE Dictionary: "slow-wave circuit - A circuit whose phase velocity is much slower than the velocity of light. For example, for suitably chosen helixes the wave can be considered to travel on the *wire* at the velocity of light but the phase velocity is less than the velocity of light by the factor that the pitch is less than the circumference."

a 75m bugcatcher loading coil is a slow wave structure with a velocity factor around 0.017 (calculated and measured).

>

Nice twist again! (That was sarcasm and take on your comment about ALL coils)

I didn't produce any MY theory. I simply realized that there is something weird (effect) when I burned heatshrink tubing on the bottom of my Hustler 80m coil, W9UCW measured and did experimenting with that and brought to our attention that there is significant difference in the current distribution across the loading coil. W5DXP put some explanations on as far as mechanism of the effect. I give credit where its due, I didn't produce any theory, I simply tried to bring attention to the effect, tried to find explanation and set the record straight for the benefit of hams, who were misled for decades (including myself), provide (with others) correction pointers so we can correctly model antennas and get better, more accurate results. If W7EL can capture the effect and provide tool to model the loading coil (lumped inductance) as what the hairpin of the same inductance does, we have a major improvement in modeling and designing loaded antennas and arrays.

Sooo, we have the effect, we have some measurements to quantify it and we have explanations going back to Dr. Nikola Tesla and we are trying to set the record straight and correct the years of false information in the ham literature, going back to J. Belrose first article in ancient QST.

What you have? Misinformation on your web site and refusing to admit that you could be wrong (again). Not answering technical questions, nitpicking on things to confuse and cloud the issue "proving" that you are right.

Funny how you object to "personal" attacks, when it is the first thing you do when someone posts something that doesn't jive with your understanding of the subject. Been there, you have done it to me few times. Tom, it's not personal attack on YOU, it is correction ("attack") on what you (wrong) say and parade on your web site.

The bottom line is, that you claim that loading antenna coil behaves according to "DC circuit laws" and has the same (or almost) current at both ends. When in reality there is quite a difference (talking about case of say quarter wave loaded radiator). The significance is, that the efficiency of the antenna is proportional to the area under the current distribution curve. If that distribution is portrayed wrongly (not showing, calculating drop of current across the coil) then we get false results, which will be magnified in multielement loaded array.
So you can keep up the mumbo-jumbo and cloud the issue all you want, reality is there and won't go away.

One more experiment that "scientwists" can do: Stick some neon bulbs at the bottom and top of the coil with equal "tail", or just move the neon bulb along the coil whil holding in your hand. I bet you would see that there is noticeable difference in brightness from top to bottom, top being brighter, meaning higher voltage. We know (not mine theory) that if voltage is higher then the current has to be lower, meaning that current at the bottom of the coil is higher than on the top. Meaning that it is not EQUAL as W8JI is insisting on. Nice science project for a 7th grader kid of a ham. (To avoid mumbo-jumbo detours - we are talking say 80m mobile Hustler or similar quarter wave antenna at resonant frequency). No need for phasors, distributed this or that, inside or outside of the coil wire and other "clouds".

Can you answer questions that are posted, instead of sidestepping them and nitpicking on unrelated stuff? That's just MY theory, I may be wrong, and I would admit it, if I am shown the right.

So can you ANSWER Cecil's question?
Where did you get the engineering degree and usage of "JI Engineering"?

That's what I would conclude from the data given. Wind some
wire around the tip top and extend the antenna by a few
inches. Then repeat your SWR measurements.

>

To understand the benefits of vertical vs. dipole, one has to look at the radiation diagram of each antenna at particular height. Vertical has the lobes, where horizontal dipole has the nulls and vice versa. The other aspect is the polarization which plays bigger role in close range signals, long range DX signals have varying polarization after they go through the path. Then there are varying angles of arriving signal depending on propagation media.
Another spect is that Vertical has omnidirectional pattern, while dipole has nulls in the pattern (off the ends).

Depends how the antenna pattern and properties fit the current propagation mode/situation, that antenna would be better. So one has to look at the antenna pattern and have idea what propagation angles and polarization we are looking for. Verticals need good ground/soil/radials/salt water for better low angle performance.

The answer to which is better: vertical or dipole is - YES, jus' depends wasaaaap (or down)!

One might also try adjusting the feed point location and see what effect
that has.

Have you a common mode choke on the feedline? J-poles are nortorious
for feedline common mode problems.

Anyone with EZNEC can answer the question for himself.
For the following EZ files, the currents at the bottom and
top of the coil are viewed by clicking on the "Load Dat"
button. Load 1 is at the bottom of the coil and Load 2
is at the top of the coil. The loads are both zero so
they have no effect on the antenna system and are used
only to report the current at that point.

I previously modeled a bottom-loaded 5.89 MHz mobile
antenna. That EZNEC file is available at:

http://www.qsl.net/w5dxp/test316.EZ

Taking that antenna and *changing nothing* except adding
1/4WL of wire to the top of the whip, yields the EZNEC
file at:

http://www.qsl.net/w5dxp/test316c.EZ

The antenna has been changed from a base-loaded 1/4WL
antenna to a base-loaded 1/2WL antenna using the same
coil in the same relative position to the source and
ground. The changes in the currents through the coil
are obvious.

The frequency was not changed so the coil occupies the
same percentage wavelength of the antenna in both examples.
In the first example, we have 1.01 amps at the bottom of
the coil and 0.6984 amps at the top of the coil. That's
fairly typical for mobile antennas at the 5.89 MHz
frequency and agrees with the measurements presented
so far.

Now, changing nothing except the whip length by adding
40 feet (1/4WL) of whip, in the second example we have
1.239 amps at the bottom of the coil and 2.068 amps at
the top of the coil. How does the lumped-circuit model
explain that one? More current "flowing" into the coil
than is "flowing" out of the coil just by adding 40'
of wire to the top of the antenna?

The coil occupies the same electrical length in both examples because they are at the same frequency. The current through the coil depends upon where it is physically installed relative to the standing waves existing at the point of installation.

Using what EZNEC tells us about the self-resonant frequency near 9 MHz, we can calculate the delay through the coil as ~59 degrees. Thus the coil occupies ~0.16 wavelength. (The wire used to wind the coil is ~0.24 wavelength if stretched out straight.) Nobody said it was a 1:1 replacement but someone said it was *NOT* a replacement at all.

I would encourage the experimenters to add 1/4WL of whip to their previously measured mobile antenna systems and make additional measurement. That is, of course, after matching the source to the new impedance. Please report the results here.

I'm always hesitant to use words like "best" for all the reasons you state, but I think that Reg qualified things pretty well. Within the qualifications of all band dipoles, the ladder-line fed general dipole is pretty darn hard to beat. I recommend them to any new hams that ask me for advice on antennas.

My rationale is that most new hams these days buy rigs that are all-band, transistorized units.These units are also sensitive to mismatches between antenna and rig. Most new hams are not antenna gurus either. So here is an antenna that will allow them to get on the air without a lot of fussing. The only real measurement caveats are some lengths that you don't want to use.

So we end up with an antenna that allows the newbie to get on the air, allows them to learn some stuff by twiddling knobs and such, then when they have a bit more experience, they can tackle that more "advanced antenna" with it's more exacting design, trimming , and measurements.

As I do now. I've really been smitten with my OCF dipole, fed with Coax, because in no small part, the feedpoint drops straight down to my shack. That coupled with an automatic tuner in my radio , allowing me to "plug and play.

But I still strongly urge newcomers to put up one of those ladder line
dipoles for the experience. They work okay, too! 8^)

Yeah! I'm trying to come up with a good test protocol that will allow me to define "work".

So far, I can note that some signals drop into the noise and become unreadable, while are readable on the other at the same time. That seems a bit simplistic though.

My main problem is the variable signal levels., and the also variable noise levels. Turns out that the antenna that was noisier on one band is quieter on another, and vice versa.

A fellow could come to the conclusion that "this ain't exactly easy". HA!

Jimbo,

The most likely source of variation is inaccuracy of your SWR meter.
It doesn't measure SWR on the feedline anyway.

The questions you should ask is does it work? And is the transmitter
roughly loaded with the right load impedance?

Reg

It isn't.

The best antenna for transmitting is the one which produces the loudest signal at the other station. The best antenna for receiving is the one which produces the best signal/noise ratio at your station. The two are often different, because they're determined by different antenna characteristics. So for starters, you can have two "best" antennas for each station you want to contact, and that "best" will vary with the skip elevation angle, local noise level, and directions and angles the noise is coming from.

Have fun!

Hm. Cecil was quick to hold up EZNEC results as evidence when they seemed to support his theory. He must have come across a situation where they didn't.

EZNEC can indeed be trusted. There are of course some cases where the underlying NEC calculating engines have limitations or run into numerical trouble, but those are quite well known and documented. So far, the models and EZNEC results I've seen here -- from Cecil's models and from the modified model I made -- are easily within EZNEC's capabilities and agree with known theory. This shouldn't be a surprise to anyone. If they disagree with some alternate theory, the alternate theory is faulty.

Promoters of antennas with magical properties often say that their antenna can't be modeled because the modeling programs don't "take into account" whatever magical effect they've dreamed up to justify their impossible claims. That's their way of trying to explain why modeling programs show their claims to be false. I detect the same phenomenon happening here.

EZNEC and NEC are being used daily by hundreds or thousands of companies, government agencies, military groups, and universities to aid in designing antennas that work, and NEC has been in use for nearly 30 years now. We make use of them daily. EZNEC is indeed trusted, by some of the biggest and most sophisticated aerospace companies and government agencies.

If anyone ever sees a significant difference between EZNEC and NEC results, please let me know so I can track down the reason.

Hello and greetings all,

I borrowed a field strength measurement equipment from the school lab.
I wanted to measure the the field strength of a low power FM
transmitter. I was told that I need to setup the antenna height
correctly. I didn't think of this. I thought all I need is the proper
antenna length and polarization for measurement. Can anyone give me
some insight regarding using the proper antenna height? Thank you.

In your set up the VSWR tells you very little!!

That 50 feet of LMR240 is modifying the actual VSWR as seen at your meter. It is not telling you the VSWR at the feed point.

First, the antenna should have a balanced feed. With coax you need a 1/2 wavelength [coax corrected for velocity factor] matching stub to keep the line balanced. This will minimized coupling antenna current on the outside of the coax cable.

Second, you should measure the antenna feed point impedance at the feedpoint, or 1/2 wavelength from the feed point [coax corrected for velocity factor].

Third, adjust the feedpoint location to get 50 + j0 ohms on your preferred frequency using an antenna analyzer [one or more members of your radio club should have one].

I'm located in southern NH, USA and if you are reasonably close I can assist in tuning your antenna.

On the contrary, Roy, it was a ***rhetorical*** question to
which Richard kindly responded. It is you who are disagreeing
with the EZNEC results, which are your own creation. I fully
agree with the EZNEC results posted below. So are you or EZNEC
correct? Both you and EZNEC be correct. Please see:

http://www.qsl.net/w5dxp/current.htm and scroll down to the bottom.

> EZNEC can indeed be trusted.

Glad to hear you say that, Roy. Does that imply that you cannot
be trusted? (Another rhetorical question) Reckon why the EZENC
results disagree with your personal postings on this newsgroup?

The matched line loss of 50' LMR240 at 146MHz is 1.5dB.

Jimbo tells us the source end VSWR at 146.2 is 2.3. One can make a reasonable estimate that the VSWR at the antenna end of the line is 3.5 (not a very good match for an antenna that should use an adjustable matching system). Total line loss is around 2.3dB, or about 0.9dB worse than matched line loss.

Now look at the tx output power, has it decreased because of the bad load. Add that reduction (in dB) to the 0.9% above to get the overall degradation of transmit perfomance.

A question: Is the proximity of other structures or feedline isolation a cause of the high VSWR, and should you resolve that before tweaking the matching?

I'm confused, wouldn't it be more important to have the right
impedance and swr at the end of the feedline, where the transceiver is
expecting 50 ohms?

Just was I was thinking when I prompted the "works" definition.

I should not be surprised if many observations indicate the better
antenna for tx is different from the better antenna for rx. I am not
trying to question reciprocity, but there are several factors, ambient
noise at the rx site probably being the most significant.

Key thing is, works is not adequately defined by making one or a few
DX QSOs!.

Mike, perhaps you need to formalise your "works" criteria with your
current experience, identifying what you need to record, before making
too many more observations.

I agree with Roy, for each antenna, rx main figure of merit S/N
(crudely S units between ambient noise and signal), and on tx, the
other stations observed S meter reading. (Whole log of issues there...
but a rough start supported by the current RST reporting scheme.)

Why the half wavelength?

The VSWR in this situation varies smoothly from the value at the feed
point to the value at the source end of the line as dictated by the
(known) line loss.

In this scenario, knowing matched line loss and the VSWR at a point,
it is possible to estimate the VSWR anywhere else on the line (as I
have done in another post).

>I'm confused, wouldn't it be more important to have the right
>impedance and swr at the end of the feedline, where the transceiver is
>expecting 50 ohms?

There are two objectives:
1. delivering the transmitter its rated load impedance (so that it
safely delivers its rated power);
2. minimising line loss.

1. is achieved by a load approximately 50 ohms at the souce end of the
line.

2. is achieved by a load approximately 50 ohms at the load end of the
line (which will also satisfy 1.).

I have done that on a j-pole that I made, but that antenna was in my
shack, where it was accessible. This antenna is in a third floor attic
where I have to wriggle my feet through 14 inches of insulation to
find a rafter to stand on. Not conducive to much tweaking.

Thanks, jimbo

SNIPPED

If you have 50 ohms at the antenna, then you will have 50 ohms
regardless of the length of coax.

A 3:1 VSWR, assuming other responses to this post are correct, means
that your antenna connection could be anything from 16 ohms to 150 ohms
and all sorts of combinations of resistance and reactance within that range.

An antenna analyzer will let you determine antenna resonance, antenna
feedpoint impedance [hopefully 50 ohms], coax line loss, and allow
proper adjustment at the connection points for your coax.

Once again, find someone in your area with an antenna analyzer. I repeat
my offer if you are within 60 +/- miles of Concord NH.

A 1/2 wavelength transmission line repeats the load impedance at the antenna with minimum loss, assuming you cannot get an analyzer at the antenna itself.

IMO, measuring directly at the antenna and solving the matching/load problem there is the easiest and best method. You are free to disagree.

It IS what the transmitter wants! But you may be introducing
un-necessary power losses in your coax from any true VSWR > 1:1.

It is possible to have a VSWR > 25:1 at the antenna and still have close
to 1:1 at the transmitter! REALLY !! Your transmitter is happy. But you
are wasting power heating the coax, not radiating it at the antenna!
This is caused by impedance transformation along the coax. VSWR ~ 1:1 at
the antenna provides best power transfer from coax to antenna.

BTW, I used to live in Kaysville and Layton [ZIP=85015] in the olden
days [30+ years ago]

Certainly, no repugnance or disrespect intended. Roy is presently
in the unenviable position of agreeing with (EZNEC and me) or
disagreeing with (EZNEC and me). Hint: rhetorical questions
require no answer.

Ok, but again you can measure the impedance anywhere and knowing line parameters, calculate Z at any other point.

Adding some length to the long leg would be relatively easy, BUT moving the feed point would be a real challenge! The coax shield and center conductor are soldered to the ladder line wires. When I tuned a j-pole in my work shop, tiny movements made a change amd maintaining the position while trying to get it soldered was nearly impossible. (At least for my clumsy fingers.) Is there a better way to connect the feed point?

Thanks, jimbo

Is the polarity of the sending station and receiving station relevant
to this discussion??
That is, a dipole sending station and a dipole receiving station would
tend to out perform a dipole sending station and a vertical receiving
station and vice versa?

Are there more stations with dipoles than stations with verticals?

I have no personal experience with your conditions.
However, the scenario is familiar. You would like to "tidy up" an
installation that is "sort of" working.

You can minimize the effort involved by going to
http://free.prohosting.com/~w0rcy/Jpole/jpole.html

That will allow you to plan the fewest trips to the attic that will
enable you achieve your goals with your resources.

OTH, if you are achieving acceptable results with what you have now I
would advise leaving it alone. If you feel 2-4db more is worth the
effort, lay out your plan!

BTW, I totally agree with Cecil. The fundamental problem appears that
the antenna is a bit short! Any change other than that is a patch!

The numbers are confusing. 50 feet of LMR240 1.5 dB, (I understand that.) Total line loss 2.3 dB. (Where did you get that?) .9 dB worse than matched line loss. (Where did you get that number?)

There is wooden structure near since the antenna is located in an attic. But I don't think there are any large metal structures close to the antenna. The coax is in PVC pipe. It may go close to a metal AC duct on it's way to the basement..

Thanks, jimbo

> THANK YO SO MUCH!

First, stop using capslock! We all hate people shouting!

2.4GHz?

If in doubt, add an extra PCB layer but be aware of the increased capacitance. 4 layers? 6 layers costs almost the same price and makes it easier to route for RF.

The Impedance seen into Power Deliver System at the device should keep low from DC to several harmonics of clock frequencies on your PCB!

Use different layers for the 1.8V and the 3.3V and try to keep the impedance well below 100milli Ohms.

Use NPO capacitors and if out of range, resort to X7R capacitors. This is not a PCB problem, more a general remark.

Reduce parasitic inductance by:

Reduce the length of via for decoupling capacitors
(i.e.reduce the loop inductance)
Change the layout of decoupling capacitors
The thickness of high frequency capacitors
Parallel the decoupling capacitors with same value
or multiple skew values

Try to get your hands on any of the nifty simulation tools from Ansoft or similar companies. Many of them have "student versions" of their packages.

Cheers

Have fun...

Cheers

> some insight regarding using the proper antenna height? Thank you.

Ron,

You need to tell what antenna type it is first.
Some antennas need to be 1/4 of a wavelength up in the air to work properly,
other types maybe 1/2 wavelength up.
Is it a vertikal, dipole or what...

Many antennas develops a high angle of rtadiation when close to the ground
and after you mounted the antenna at the correct height, a totally
different radiation pattern develops.

So there are no simple answer to your question Ron, not without more
information.

Cheers

Dan / M0DFI

Ok.
> Total line loss 2.3 dB. (Where did you get that?)

It can be calculated knowing the line loss and source end VSWR. The
additional 0.8dB is increased line loss due to operation with VSWR>1.
Try http://www.vk1od.net/tl/tllce.php for the calcs.

> .9 dB worse
>than matched line loss. (Where did you get that number?)

Sorry, my rounding error, call it 0.8dB. It is by subtraction of the
matched line loss from the total line loss.

Dave, there is no doubt that the closer you are to the antenna, the
less error introduced by tolerance on line parameters. On the
otherhand, the instrumentation / user can be disruptive or real
inconvenient.

As for the calcs, one can be lazy and use
http://www.vk1od.net/tl/tllce.php (if one's cable type is supported).

My antenna analyser can't do the calcs internally, I don't know if
some can, but it would be a pretty handy feature.

Sorry for the confusion. The ladder line is the j-pole antenna. Cut to
the appropriate length, etc. The coax feed line is attached to the "J"
near the bottom, maybe 2 inches up.

Thanks, jimbo

Well, the thing operates OK as far as I can tell. But it doesn't take much to hit a 2 meter repeater. I guess I am more concerned about damage to the transmitter than I am about getting full power radiated.

Thanks, jimbo

> >> band?
> >>
> >> Thanks for any insight, jimbo

Seems to me there are several items being asked / answered here. Sort
of going backwards through the parts of the thread I can see...

1 - I think it is a safe bet that if the VSWR at the transmitter
(regardless of feed like loss BUT within normally expected values) is lowest
at the high end of the band, then the antenna system is either too short or
resonant too high in frequency - take your pick of wording.

2- As you measure VSWR further and further from the load (antenna) you will
get a better and better value because of the loss in the transmission line.
This is because as signal is lost to the loss (attenuation) of the line,

there is less to reflect at the load and less makes it back to the measuring device - when compared to tehat sent from teh transmitter. Less power to measure in the backward direction = better VSWR.
Side Note that the loss is twice the line loss in this case, because it travels it twice in a round trip. Another result of this is that a simple resistive (lossy) attenuator (or a hunk of t-line used as an attenuator) has a return loss that is equal to twice its attenuation rating. In other words, a 10dB pad has a 20 dB return loss and is a pretty good load, since only 1% of the power makes it back to be measured for the VSWR measurement.

3- Then there are comments about measuring an *impedance* *at* the load, or 1/2 wavelength away. This is because the *Impedance* repeats every half wavelength in a *LOSS-LESS* line (due to the much discussed physics of waves). For practical lines, with minimal loss, it's pretty close, but, as explained above, approaches 50 ohms (Zo) further and further from the load. Therefore, accuracy in the measured *impedance* degrades further and further from the load.

But/out flag set//

Richard,

This is cute. Both the ice/oil metaphore and the tax round off issue.

I think Roy's comment was interpreted as saying that "skin effect does not
occur for thin conductors" It was meant that with a thin conductors, the
skin effect is there, BUT it is such that you *can consider* the current
density as being nearly constant and therefore can be handled by using
resistance which will be almost the same as that at DC.
Does that do it Roy?

> and by how much.

The metal thickness is awfully thin on this material...VERY thin. This
means a high resistance. ou should be able to measure what ever you have
and see what the DC resistance is. The DC resistance should be the
MINIMUN you should experience in teh RF domain, right.
When you say "adding more area" I think you mean to say that you simply make
the Mylar "strip" *Wider*, right. Well, wider means that it'll prpbably
have a broader bandwidth also. Now, the key here is whether you can widen
it enough to make up for the thin material.
I ask if the use of a "strip" of conductor will experience something of a
skin-effect-like effect because teh current will tent to force itself out to
the edges of teh strip for the same reason skin effect occurs... starte to
hurt my brain a this point.

I see this as possibly the most effective
> change with respect to radiation since we now have forced more current

> not changed.
> I find it difficult to accept that
> the decay rate has changed

I don't think it was meant that the decay rate changes. The effect has to
still be there. It is that with a thin (compared to skin-depth) conductor,
the change in current (density) with depth doesn't change much before you
run out of conductor, therefore it can pretty much be ignored. Also, for a
round conductor, remember that the decay rate from the two opposite sides
will collide with each other. So that it starts to decrease, but half way
through it "hits" the other :skin-depth current" and it starts back up
again.

> and intuatively I would have thought the surface current
> would increase significantly.

This I don't follow.

I'm not sure what that is all about, but Cecil....there are over 550 posts in this thing now.

Can you state in a few clearly written lines what you have learned or concluded? If that is too involved, that's OK.

I'm just trying to understand what you point is in all of this, and where your head is at after all the posts.

My conclusion for short mobile or fixed location loaded antennas is:

1.) If a loading coil has compact form and is terminated in a capacitance that presents a reasonably low impedance compared to inductor capacitance to the outside world, current taper will be minimal. As a matter of fact, it can be immeasurable.

2.) Current taper and phase shift do not correspond to the electrical degrees the loading coil "replaces", except as the physical size of the loading coil might increase stray capacitance to the outside world.

3.) Phase shift of current is anything from zero to a reasonably small number of degrees, and does not correspond to the electrical degrees the inductor replaces.

4.) There are at least two ways to get a good answer. One is by a circuit model with enough L and C sections, the other is with a wave theory approximation. Both models have limits.

I think that pretty much is it. What did you conclude? Can you get it into a few clear words?

I just want to see how far apart everyone still is.

> minimal. As a matter of fact, it can be immeasurable.

Current taper depends upon where the coil is installed in the
standing wave antenna system. It can be flat, positive, or
negative. If properly placed, it can even have current flowing
into both ends of the coil at the same time, i.e. a 180 degree
phase shift in the currents at each end.

The coil distorts the current waveform away from the pure cosine
envelope presented by a 1/2 wavelength thin-wire dipole but then
so does a large diameter conductor.

> 2.) Current taper and phase shift do not correspond to the electrical
> degrees the loading coil "replaces", except as the physical size of the
> loading coil might increase stray capacitance to the outside world.

Phase shift corresponds to the delay through the coil.
It can be estimated from the self-resonant frequency
measurement where the delay is known to be 90 degrees.
This is a common method of estimating the delay (electrical
length) of a transmission line stub.

> 3.) Phase shift of current is anything from zero to a reasonably small
> number of degrees, and does not correspond to the electrical degrees
> the inductor replaces.

My 75m bugcatcher coil occupies about 60 degrees at 4 MHz,
2/3 of the electrical length of the antenna. 60 degrees doesn't
seem to meet the definition of "reasonably small". IMHO, that
would qualify as "reasonably large", i.e. more than half the
electrical length of the 75m mobile antenna.

> 4.) There are at least two ways to get a good answer. One is by a
> circuit model with enough L and C sections, the other is with a wave
> theory approximation. Both models have limits.

It is impossible to get a good answer with a model that presupposes
faster than light propagation through the coil with equal amplitudes

and phases at each end of the coil. The error is the same as assuming such for a piece of transmission line. Dr. Corum's suggested crossover point where the lumped-circuit model fails is 15 degrees or 0.04 of a wavelength. Either the distributed-network model or Maxwell's equations must be used beyond that point in order to obtain valid results.

> I think that pretty much is it. What did you conclude? Can you get it
> into a few clear words?

A 75m bugcatcher coil is a "slow wave structure" described by Ramo and Whinnery, by the IEEE Dictionary, and by Dr. Corum. The velocity factor of my 75m bugcatcher coil has been measured at ~0.017 which agrees with the published formula.

Yes. After art misinterpreted what I originally said (that you can ignore skin effect when the thickness is small enough), I said explicitly just what you did. Maybe it'll sink in a little better after having been said once and explained twice.

>
> Thanks, jimbo
Connect your feed points to the Jpole using clamps. Adjust the location
of the feed point and the characteristic impedance by moving the clamps.
You do not have to adjust the length of the feed line until you fine
tune the feed point impedance.
I just finished making the collapsible jpole antenna that was featured
in QST last spring. When I first tested the impedance it was way off.
All I had to do was loosen the clamps and bump the clamps up and down
the pole to obtain optimal settings. Due to the out of ham band use I
will be putting the jpole to the SWR at my xmit freq. is higher than I
would like the midpoint SWR is about 1.1:1.
This is why Antenna design is an ART not a SCIENCE.

********** REPLY SEPARATOR **********

Nitpicker alert:

1. You should have not limited the "NO" to HF. Six meters is also a
"NO" for ionospheric skip.

2. Polarity of the signal for ground wave (not surface or space wave)
is indeed important. Vertical polarization works best. Horizontal is
rapidly attenuated.

Generally when you place TX and RX antennas above the ground
and you change the height of RX antena, you see the variation of
signal strength. This is due to the ground reflection and we call
it "height pattern." Probably your manual suggests this influence.
How to avoid this? (although both methods do not give rigorous results,)
1. You may take the average of height patten.
2. Make the distance short between the antennas.

> OK, so you have no theory and I assume no opinion.
> Good enough.
> 73 Tom
>

That just about summarizes you. You don't need theory, just go measure it as I described. The theory started with Dr. Nikola Tesla and skillfully defended by W5DXP. I don't claim to steal anybody's theory, other people came up with explanation of the effect, I am just defending it based on reality, burned coils and not coming up with "theory" that would back up wrong claims.

What the hell is all the discussion about? Your misinformation on your web site, and you can't allow to get it right, because you can't possibly be wrong or admit to it.
Just crap, no answer to technical questions, defending your baloney. What's your theory? RF behaves like DC in a loading coil?

ANSWER the frickin questions!!!
You can't, because you either don't get it or your ego doesn't allow you to get it.
Pretty sad picture. I have no more to say, if you have no answers. I get better response from a brick wall.

Just don't claim to be engineer or "JI Engineering". Engineers do not behave like that, they have certain code of ethics and rules on usage of term engineer and engineering. You might want to check with Georgia Engineers association.

I am sorry about all this, but I just don't take a crap and for the umpteen time, it just gets too much. Man who attacked misinformation on Interned on QRZ pages is guilty of the same. K7GCO has a name for people like that: "Technical imposters".

Sayonara!!

Cross-polarization losses are in the neighborhood of 10-20 dB at VHF and above. With my license, I cannot do HF, so others may chime in with those numbers. Assuming ... there's that word ... that the random polarization variations ("rotations") are around some central figure, during for a given QSO, then one antenna will work better -- the one that happens to be optimum for that path and for the antenna on the other end of the QSO.

There exists a phenomenon that I do not understand well, called Faraday rotation, where an EM wave passing through a magnetic field will undergo a polarization "alteration", so to speak. Thus, two verticals on the ends of a long-distance QSO might not perform as well as if one were a vertical and the other a horizontal -- due to the Earth's magnetic field.

Great job Steve, you kept to the subject which was dealing with extra
thin conductor material
backed by an insulator which I mentioned earlier
ve must consider both sides.
Now I am with you all the way except the part you don't follow and the
question as to what happemes at the conductor and insulator interface.
Now to the last point regarding current at the surface. First we can
say that decay is negligable
so can we state that radiation resistance
has risen? Can we say surface current has risen over and above when the
conductor was thick?
Remember Steve I started this thread
there was a problem with my understanding and I am looking for where I
am in error, not defining what actually happens. Now let me add
a further step which probably bring about howls.
We have broadened the width of the element significantly. We have
limited penetration depth of the current where decay is negligable and
"all" current is at the same phase.
The field generated by current reaction
is close to a hundred percent efficient
and actually now closely conforms to a true reflector as Terman
describes. So what exactly
are we left with and are we gyrating towards a dish antenna where like
a reflector or mirror
we can now "focus" energy?
And what happens at the conductor insulator interface? Is a field
generation at the rear prevented by the insulator such like a true dish
there is no field other than spill over?
Steve you have kept within the confines
of the question as enunciated in my first post so I would appreciate
you following up on these final thoughts.
Very best regards
Art.

Hi all

I have a MFJ-207 Antenna Analyzer taken at our last weekend hamfest.

Good unit but I bet there is a group of out there that passes good
modifications for this unit.

Some right out of my head.

1 Use a PLL to lockup the carrier down to 10KHz

2 provide for either FM or AM modulation, as well as CW.

3: A method to detemine the impedance of the antenna, most all of us
should have access to a low band scope.

"The unwillingness of the "gurus" to answer specific
technical questions is pretty disappointing."
- a comment from a reader.

You said you could use the lumped-circuit model to explain
how the current at the top of the coil could be greater
than the current at the bottom of the coil as it is
at the bottom of the page at:

http://www.qsl.net/w5dxp/current.htm

If you are technically correct, why are you so technically
silent on the subject? Does the emperor have no clothes?

At least a dozen of my technical questions have gone
unanswered by being ignored. Lot's of readers have
noticed and commented in emails to me.

If you will repeat your measurements with 1/4WL added
to the top of the base-loaded mobile antenna, you will
start to understand the physics involved. The current
taper through a coil depends upon where in the standing
wave environment that the coil is installed.

The lumped-circuit analysis fails for the typical
75m amateur radio mobile antenna.

Thanks for all of the advice. I have one more question. Can I tune a
J-Pole antenna in my shop and then move it to the attic and expect the
same performance? In other words, is an antenna an antenna or is an
antenna and it's installation an antenna?

It would seem to me that if the antenna is tuned and works in my shop
it should work in the attic. Otherwise, how do "store bought" antennas
work?

Thanks, jimbo

3214. 2.4ghz inverted V?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-21 13:53:32 UTC
From: KG0WX <kg0wx@yahoo.com>
Message-ID: <1142949212.274524.78430@i40g2000cwc.googlegroups.com>
Source record: 62675

Will the classic inverted V work on 2.4ghz (802.11b/g WiFi)?

I just installed a mini PCI WiFi card in my T23 laptop and routed the two coax cables from the card to the back of the LCD screen. I needed two temporary antennas and it dawned on me that maybe a pair of inverted V antennas might just work, at least on a temporary basis until I get a high gain sector antenna built or even a Bi-Quad setup.

I made each leg on the two antennas 30.5mm long. The coax runs straight down from the feed points about 4" then snakes it's way back inside the laptop. The whole shebang is just taped to the back of the laptop.

Will this work? Any problems? What about gain?

Ken KG0WX

> unanswered by being ignored. Lot's of readers have
> noticed and commented in emails to me.

So what?

1.) I told you weeks ago I'm too busy working right now to get deeply involved in this.

2.) When measurements are made, you dismiss them as "measuring current in a system with standing waves".

> If you will repeat your measurements with 1/4WL added
> to the top of the base-loaded mobile antenna, you will
> start to understand the physics involved. The current
> taper through a coil depends upon where in the standing
> wave environment that the coil is installed.

Then why can I measure a fixed inductor location in a dfixed antenna, and range from no taper at all in current to just under 1/3 reduction in current? Does you standing wave model explain this very repeatable measurement?

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

> The lumped-circuit analysis fails for the typical
> 75m amateur radio mobile antenna.

I disagree. Unless we want to say so does the standing wave model.

The antenna can be modelled as a series of lumped inductors with capacitance to the outside world just as well as any other method.

You can tune a J-Pole antenna at one place in free space, move it
to another place in free space, and expect the same results. The
real world is not so forgiving. The conditions will not be
identical but they may (or may not) be close enough to be
acceptable to you. Welcome to the real world of ham radio.

You are silent on the subject of how the lumped-circuit model
explains more current at the top of the coil than exists at
the bottom of the coil. Please share that knowledge with us.

> I think I've done a good job of explaining things, and I've made

Have you made measurements with 1/4WL added to the top of
a mobile antenna? Will you believe your measurements when
you measure more current "flowing" into the bottom of the
coil than out of the top of the coil?

It has been proven beyond a reasonable doubt that standing wave
current, func(kx)*func(wt) is not like traveling wave current,
func(kx +/- wt). Since standing wave current phase is devoid of
phase information, its phase cannot be used to determine the phase
shift through a coil. Standing wave current phase is what W7EL
measured. He drew conclusions about phase from measuring the
phase of a signal devoid of any phase information. I pointed
that technical fact out to him at the time and he ignored me.
I also pointed out that the phase information was actually
embedded in the amplitude measurement as a variation of a
cosine function. He rejected that assertion with a personal

remark.

>>If you will repeat your measurements with 1/4WL added

> measurement?

Of course! If you measure the current taper at a point where the standing wave current slope is near zero, you will measure near zero taper. If you measure the current taper at a point where the standing wave current slope is near maximum, you will measure lots of taper. If you measure at just the right point, you will measure current flowing into both ends of the coil at the same time. That's another thing I have asked you to explain with no response.

>>The lumped-circuit analysis fails for the typical
>>75m amateur radio mobile antenna.
>
> I disagree. Unless we want to say so does the standing wave model.

The "standing wave model" is a component of the distributed-network model which is known to work in the presence of standing waves. The lumped-circuit model is known to fail in the presence of standing waves. Quoting Dr. Corum: "There are no standing waves on a lumped element circuit component. (In fact, lumped-element circuit theory inherently employs the cosmological presupposition that the speed of light is infinite, as every EE sophmore should know. See, e.g., - "Electric Circuits", by J.W.Nilsson, Addison-Wesley, 1983, p. 3."

Dr. Corum's first sentence above means: *There are no standing waves *allowed* in a lumped element circuit model.*

> The antenna can be modelled as a series of lumped inductors with
> capacitance to the outside world just as well as any other method.

But that is not what you and W7EL have done. You have modelled it as a single coil with distributed capacitance. That approach is known to fail when the coil is longer than 15 degrees and installed in a standing wave environment.

If you use enough lumped inductors and capacitors, you have the distributed network model but with a lot more math to do.

Hi Tom,

You may be shocked to discover this, but it is possible that my comments have been reproduced slightly out of context.

At the time, Cecil was still clinging to the notion that if someone did the measurements properly they could elicit the original phase information contained in the traveling wave components. In particular, the space and time coupling represented by the traveling wave function, cos (kz - wt), was merely hiding. He has since changed his mind, and unfortunately I seem to have become one of his quotable gurus on this topic.

A major part of the ongoing debate is the careless use of "phase" as if it has a single definition. I have counted at least five different uses in this thread, all correct in their own way, and none interchangeable.

I won't try to explain further. My level of understanding of phase and such matters is fully satisfactory for me.

Sorry, Gene, you misunderstood what I was saying. That's why you
accidentally posted technical information that supported my side
of the argument without realizing it at the time. (Remember, I said
you were a genius for posting it and I thank you.)

What I previously said was: If the reflected wave could be eliminated,
as in a traveling wave antenna (like a terminated Rhombic) then
we could measure the actual delay through a loading coil using
the forward traveling wave, the only wave left in the system.

Here's one leg of a terminated Rhombic:

source------------////////------------------load
coil

When I said the delay through a coil could be measured using a
traveling wave, this is what I had in mind.

I am often thinking faster than I can type and wind up not
expressing myself very well. This time, your misunderstanding
worked out to my advantage because it prompted you to post
some technical facts in rebuttal to what you assumed I said.
Your and Tom Donaly's technical facts were instrumental in
getting my point across and I thank you both for that. You
two seem to be the only ones posting who understand the
physics implication of func(kx)*func(wt) Vs func(kx +/- wt).
Thanks again.

Gene, W4SZ wrote:
"A major part of the ongoing debate is careless use of "phase" as if it has a single definition."

If Gene has counted at least five different uses in this thread, what are they?

Phase is defined as 1) The angular relationship between current and voltage in alternating-current (a-c) circuits. 2) The number of separate voltage waves in a commercial a-c supply such as single-phase, three-phase, etc. 3) The time that has elapsed measured from some origin as a frection of one complete period of a periodic function.

I don`t think the problem in the debate is that the participants don`t know the circumference of a circle is 2 pi radians or 360-degrees, or that 360-degrees equals a complete period or one wavelength.

The problem is that some participants don`t admit their mistakes and hope they are unnoticed or can be hidden by plenty of nonsense. J.J. Rousseau swore to consecrate his life to the truth. So did Lucy Ball, but she recommended fibbing about one`s age. It is hard to keep a vow to be truthful but it is good for the environment.

Too many here struggle for status by hook or crook and fib when the truth would work better.

Best regards, Richard Harrison, KB5WZI

Hi jimbo

The second, the wire you call an antenna, its method of feed, and its environment are the radiator. With care, it may work straight out of the box, but your numbers already offer a different story; thus the question becomes "what constitutes care?"

>It would seem to me that if the antenna is tuned and works in my shop

The market for antennas destined to be put in an attic is very small, hence you see very few for sale.

Gain? Hope you are expecting anymore than from a classic inverted V.
Problems? The usual like common mode - consult how to build a choked
feed.

Would you likely notice any problems if you built your inverted V to
your size? Probably not. If you did, it is more likely a problem of
not enough power/sensitivity, Fresnel issues, or poor sight lines.

Hi OM,

The solution to your problem is found in describing your problem. You
need to provide more information:
What is the land like around you?
What is the land like between you and your station?
How high can you put the antenna?
How far away is the station?

Hi Richard,

Adding to the 5 ways to spell phase, we could add to your list to fill out the 7 deadly sins.

Anyway, it seems one other use of "phase" appears to be in the 90ï¿½ and that part missing and presumed taken up by the coil. Who knows, the landscape is littered with fulminations as you've noted and all have been pressed into service.

It's really very simple. It functions as a series of L or T networks
with series inductance and shunt capacitance. There isn't anything new
or novel about this.

> > I think I've done a good job of explaining things, and I've made
> > measurements and posted results.
>
> Have you made measurements with 1/4WL added to the top of

No, because it is outside the boundary of the antenna being discussed.
We have been talking about short loaded antennas. Not full sized
antennas, not inductors that are nearly self-resonant (tesla coils), or
antennas with distributed loading (helical antennas).

That's an entirely different topic.

>Will you believe your measurements when
> you measure more current "flowing" into the bottom of the
> coil than out of the top of the coil?

If the inductor is nearly self-resonant or in a mode where flux
coupling is low compared to termination impedance, certainly odd things
can happen. RF plate chokes commonly go into modes like that when they
have large inductance to cover the bottom of HF, and have to function
at upper HF also. None of this is rocket science require standing wave
analysis.

As a matter of fact at the first series resonance an RF plate choke can
be accurately analyzed as a pair of back-to-back L networks.

This stuff really isn't new or fascinating Cecil.

> It has been proven beyond a reasonable doubt that standing wave
> current, func(kx)*func(wt) is not like traveling wave current,

So what?

The issue was actual current flowing, not reflected wave current that
only would be a factor in a transient condition.

It almost seems like you are claiming we cannot measure the current causing loss or causing radiation because of "standing waves". That's nonsense of course, and I'm sure most people realize it.

Most people probably understand a current transformer will indeed measure current that causes radiation and heat loss.

You're right, Gene, I'm shocked! shocked! to learn that Cecil might distort anything anyone might write. I never for a moment, though, thought there
was anything wrong with your understanding. It was Cecil's understanding of your understanding that was in doubt.

> or novel about this.

Yes, there is. If you have to resort to multiple series-Ls
and multiple series-Cs, then you are having to resort to the
DISTRIBUTED NETWORK MODEL which is what I have been telling
you for years.

> No, because it is outside the boundary of the antenna being discussed.

Heaven forbid that we discuss anything outside your super
narrow boundary conditions. Tom, there is a world of laws
of physics outside your narrow boundaries and you were even
wrong inside your own narrow boundaries. The delay through a
coil is fixed by frequency and does not depend upon the
electrical length of the antenna being 1/4WL (or 1/2WL).

Please see: http://www.qsl.net/w5dxp/current.htm

> That's an entirely different topic.

Sorry, the laws of physics work no matter what the topic.
In TX and LA, what you are doing it is called "crawfishing".
When a crawfish feels threatened, it swiftly tucks tail and
runs for the nearest cover. That's exactly what you are doing.
Don't you guys have crawfish in GA?

> If the inductor is nearly self-resonant or in a mode where flux
> coupling is low compared to termination impedance, certainly odd things
> can happen.

No, they are not ODD! They are the laws of physics. The fact
that you think they are odd just shows your ignorance of those
laws of physics. You can't seem to climb out of that bottomless
lumped-circuit hole in which you live.

>>It has been proven beyond a reasonable doubt that standing wave
>>current, func(kx)*func(wt) is not like traveling wave current,
>>func(kx +/- wt).

>
> So what?

Spoken like a member of the unwashed masses whom you are trying
to snow. Before you embarass yourself any more, please ask Gene
and Tom what that means in reality. They are on your emotional
side but I doubt they will choose to support your technical
ignorance. I assume you have read, "The Emperor's New Clothes"?
Tom, sad to say, you have no clothes.

> The issue was actual current flowing, not reflected wave current that
> only would be a factor in a transient condition.

Sorry, Tom, reflected current is a reality in a *standing wave* antenna.
Why do you think they call them "standing wave antennas"? To imply
that standing waves exist on a standing wave antenna only during
a transient condition is, well, pathetic. This illustrates, better
than anything else, why you are confused.

> It almost seems like you are claiming we cannot measure the current
> causing loss or causing radiation because of "standing waves". That's
> nonsense of course, and I'm sure most people realize it.

What I am claiming is that the standing wave current phase doesn't
contain any phase information. Gene and Tom have agreed. Why are
you disagreeing with all of us?

> I can't explain a problem that exists only in your mind.

The problem exists in reality and has been documented through the
years over the past century by brilliant engineers. What is hard
to explain is a solution that exists only in the mind of W8JI and
nowhere else.

Tom, are you retracting what you posted? If so, just come right out and say so. Otherwise, you are going to have to live with the reality that what you posted agrees with my side of the argument and disagrees with W8JI and W7EL. Both of you guys say there is no phase information left in the measured phase of the standing wave current. Do you wish to retract your statements? Since W7EL measured the phase of the standing wave current and drew illogical conclusions from that measurement, are you guys going to support W7EL's conclusion or support the technical facts that you posted previously? Please choose.

Seems to me you are caught between supporting the irrationality of a friend or the laws of physics. Please choose the technically correct side. Ham Radio will be better served by that decision.

I think Reg's ONLY qualifiers were "all round, all band" (presumably
meaning 80 thru 10). To me, that description falls well short of the
mark, as "qualifiers."

> Within the
> qualifications of all band dipoles, the ladder-line fed general dipole
> is pretty darn hard to beat. I recommend them to any new hams that ask
> me for advice on antennas.
>
You can make a good case for this proposition. But I'm a bit puzzled
on how these qualify as A-1 newbie antennas.

First, our newbie to learn how to coddle finicky ladder line, bring it
into the shack, and make the transition to unbalanced feed. Then he/she
needs a crash course on transmatches:
1. Balanced or unbalanced design? (If unbalanced, may not work well
with this antenna; if balanced, may not work with future, coax-fed
antennas.)

2. Low or high power? (If low, may need to upgrade later.)
3. Manual or automatic? (If automatic, how interface to rig?)
4. Which brand and model? (Might Fine Junk or $quality$?)
5. New or used?
6. How do you operate the transmatch?

If our newbie wants some power-handling capability, and plans
to buy it new, he/she will need an extra 500 to 700 USD and more
space on the desk.

Re Reg's reference to a choke balun: I've been looking for good quality,
commercial choke baluns equipped with SO-239 inputs and outputs.
So far, I haven't found any; and I haven't been quite motivated enough
to make one. What should our newbie do to get one, if needed?

> My rationale is that most new hams these days buy rigs that are
> all-band, transistorized units.These units are also sensitive to

> either. So here is an antenna that will allow them to get on the air
> without a lot of fussing. The only real measurement caveats are some
> lengths that you don't want to use.
>
I can't quite see how slogging thru all the above is going to be easier for
a newbie than buying a Buckmaster OCF or basic trap dipole, buying a
ready-made coax jumper of the required length, and then doing plug-
and-play with the (typical) rig's built-in auto-tuner. But it probably
would
be more educational.

> So we end up with an antenna that allows the newbie to get on the air,
> allows them to learn some stuff by twiddling knobs and such, then when
> they have a bit more experience, they can tackle that more "advanced
> antenna" with it's more exacting design, trimming , and measurements.
>
I'm having a hard time figuring out what antenna type(s) would be "more
advanced" than the random-length-doublet-with-outboard-ATU, and
yet require more fiddling.

But I will grant you this: IF someone decides from the get-go that they
want a glitzy transmatch at their operating position--whether they need
it or not--then the balanced-feeder doublet makes pretty good sense.
This would be especially true if there wasn't enough space for something
like a Buckmaster OCF, but there was enough space for (say) an 88'
doublet.

I picked up a Oct 1973 issue of 73 & noticed a interesting article on
a mast mounted rotatible very
hig gain 435mhz antenna, cheap and easy to built. Ive been trying to
build a high gain antenna to
recieve ATV in the 903-928 band & seems this maybe the one. The claims
for
this antenna seem streached abit, they claim 26dB gain from just wire
and a few resistors
and claim its 435mhz design can work up to 890mhz, theres even a quad
rhombic shown
also. Sounds to good to be true, so i wandering if anyone has had any
experience with
actually building & using one of these antennas. I would like to build
some kind of high gain recieve
only antenna to see if its possible to get a decent signal from some
of the ATV repeaters.
Seems here in western N.C. the ATV activity is located mostly in this
located band.
Thx N4aeq

Hi OM,

It's as good as any other.... Good being highly qualified, especially
as the construction details are so shy of description here. Barring
those details, rhombics are not a mystery.

If it works on the 440 Band, you can scale it down for the 900 band if
you want it shorter, or just use the instructions provided. How good
it performs remains to be tested. You would have to test anyway to
confirm any antenna claim for gain.

Also I would check to make sure the gain is listed as 26 DBd instead of DBi.
Back in the day, allot of companies inflated their specs by stating the
DBi gain instead of DBd.
DBi being gain over an isotropic and DBd being gain over a dipole.

You guessed it. This antenna has been thoroughly debunked in the 33
years since the original article.

I don't have detailed references, but the story goes that ground gain of
6dB was added on *twice* to the claimed original free-space gain
figure... which was optimistic in the first place.

At 26Db there isn't enough difference between dipole and isotropic to
matter.

Hi,

What would anyone recommend for measuring SWR on a system that has a low power transmitter (20mW) ?

My meter has lowest range of 3W FSD. I do have a digital power meter and directional coupler, would it be best to manually measure fwd power and reverse pwr and calculate SWR ?

Thanks in Advance

Regards

David

Source record: 62606

To get 26 dB over a dipole would require rhombic leg lengths of about 125 wavelengths, or about 275 feet at 450 MHz. The overall length would be around 500 feet. The beamwidth would be so narrow you'd have difficulty getting it aimed toward one station, even if you were able to turn it somehow.

Roy Lewallen, W7EL

Hi Richard,

I am not going to spend any more time on this topic, but I will answer the "5 phase" question. I am not going to try for extreme precision, so I suspect the nit-pickers will have a field day.

1. The classic relationship between current and voltage in a reactive environment.

2. The time and space connection in a traveling wave, the "kz-wt" term.

3. The amplitude shape factor in a standing wave, the "kz" term.

4. Fixed offsets that effectively show different starting times for waves. For example, "kz-wt" vs. "kz-wt-d".

5. The sign reversal every half-wave on a long antenna. This is merely a reflection of the periodic nature of a cosine function, but it is often called a "phase reversal".

There are more, I am sure, but these are the ones that I specifically saw in the first 1000 or so postings in this thread.

73,
Gene

20mW is definitely pushing it. QST published a QRP SWR meter at one point that might go down that far with work. I use an RF noise bridge and a receiver for establishing feedpoint impedance -- that may be the way you'll want to go.

IIRC the bridge design came out of "Solid State Design for the Radio Amateur" by Hayward and DeMaw. I think it's basically what MFJ sells, only they wrap it all with a fancy computerized controller.

Very difficult to measure on an antenna.

> 2. The time and space connection in a traveling wave, the "kz-wt" term.

Can be used to measure the delay through a loading coil.

> 3. The amplitude shape factor in a standing wave, the "kz" term.

Can be used to roughly estimate the delay through a loading coil.
The "wt" term of the standing wave cannot be used to measure
the delay through a loading coil.

> 4. Fixed offsets that effectively show different starting times for
> waves. For example, "kz-wt" vs. "kz-wt-d".

Or the difference between the phase of a traveling wave entering
a loading coil and that traveling wave exiting the loading coil.

The same thing happens in a transmission line with reflections.

On the upstream side of the diodes (if any) in the directional
coupler, you might be able to obtain AC measurements proportional
to the forward and reflected power, depending upon the sensitivity
of your meter. It could also be done using an o'scope.

Cecil, this reminds me of an old Groucho line that goes something
like, "Who are you going to believe, me or what you see with your own
eyes?" You're expecting me to believe what you thought up in your head
over what Tom Rauch and Roy saw with their own eyes. This whole thing
boils down to an engineering question, anyway, which is, is it possible
to engineer a loading coil to be small enough at the lower end of the
HF spectrum so that it can be modeled using network analysis? Tom says
he can do it, and he's posted the results of his research efforts on
the web. He hasn't had to rely on sophistry, selective quotations,
huge numbers of irrational posts, threats, unproven theories, or
anything other than numbers derived through carefully done
experimentation to make his point. When you can do likewise,
Cecil, you won't have to act like a lunatic to make your point,
the numbers will do it for you, and the rest of us will be spared
the spectacle of watching you defending, with your last breath,
something you aren't willing to take the time to even fully understand.

This gain figure sounds very much like the 144MMz EME double rhombic
that was in the ARRL handbook for years. As I remember it was "attacked"
some years ago for claiming such a high gain.

I built one for 70cm some years ago and the results were disappointing,
or rather not as good as a 22 el loop quad. I didnt do much
experimenting with it sorry.

I suppose then I then should just measure forward power from the incident port and then tune the antenna while monitoring power on the reflected port (of the directional coupler) for min. reflected power.

I should have also mentioned frequency is 900 MHz.

What they saw with their own eyes is a mistake that you apparently
would never make. Roy tried to measure the delay through a loading
coil using the phase of a standing wave. As I understand what you
and Gene have said, that is impossible since the standing wave phase
doesn't contain any useful phase information.

> This whole thing
> boils down to an engineering question, anyway, which is, is it possible

> he can do it, and he's posted the results of his research efforts on
> the web.

False, Tom has refused to use network analysis. That's the whole
problem. His lumped-circuit model assumes faster than light
propagation through every coil. His 3 nS through a 100 uH coil
is getting very close to faster than light speed.

Just today, Tom made a posting that indicates he still believes
that Func(kz)*Fun(wt) is the same thing as Func(kz +/- wt). My
measurements are the same as Tom's. Only one of the dozen or
so measurements made by everyone had the currents equal
at both ends.

Please look at Figure 3 at:

http://www.k6mhe.com/n7ws/Loaded%20antennas.htm

And please explain again how 1 amp is equal to 0.65 amps.

Source record: 62618

There are two transmission lines in cascade plus a load impedance.

The first line can be considered to be the main line from the
transmitter.

The second line can be considered to be an impedance matching
transformer between the first line and the antenna.

What is the impedance and length of line in the transformer if the
antenna feedpoint impedance is not purely resistive?

What are the input impedances of the two lines, R+jX ?

What percentage of transmitter power is dissipated in the two lines?
What is the overall power efficiency?

The answers can be found in new program TWOLINES.

SWR is not involved.

Download program TWOLINES from website below in a few seconds and run
immediately.

Exactly what i wanted to know, i may hold off on this one and search for a different type high gain uhf antenna. Only problem is all the design programs i have found on the web for yagi or log perodic antennas are for 6-8 elements maximum, @ 900mhz i would like to have as many elements as a boom would support. So my next question would be where to look for a multi element beam using atleast a minimum of twelve elements?

You might try modeling the antenna or rading a textbook that covers
real Rhombic antennas.

Antennas and Transmission Lines by John (jack) Kuecken is a great
place to start.

I think what you will find is that gain figure is extremely inflated.
It is unobtainable in the real world. I'd expect more like 15dBd
maximum gain if you can do almost everything perfectly, and you might
squeek another 3dB with two Rhombics in optimum configuration.
At the old VOA installations, the very large Rhombic antennas had less
gain than curtain antennas that occupied much less space.

I have a 300 foot tall support. I've been trying to model an Inverted V
or V beam with useful gain over a small Yagi without success. If
anyone has sucessfully modeled one, please let me know.

Hi Tucker

I had to re-look at the month that article was published to be sure it wasnt an April 1 issue.

The antenna's beamwidth, with a circular cross section, will be close to 10 degrees maximum. It is likely that a 12 foot diameter dish would be the minimum size that would provide that 26 dB Gain at 900 MHz. That gets pretty difficult to make stable when also rotateable.

I would suggest that you start with a Yagi and try it. You'll soon know if that gain is adequate. And the money spent on parts wont hurt your pocketbook. I sure wouldnt expect you to jump into antenna design with a beginning project of building a 26 dB Gain rotateable antenna.

Jerry

Scaling shouldnt be an issue so start by looking at 1296MHz antennas.
You can always computer model them as well. Have a look at Mr Cebiks'
website. (http://www.cebik.com) I'd actually recommend you look at a
corner reflector. Nowhere as critical as a yagi and pretty easy to
build. Maybe even a 3D corner?

I've been wanting to try a Sterba curtain (on 900mHz) over a planar
reflector. That wouldnt be real critical either.

Yes!

Feeding at the "bottom" makes it horizontal and the "side" vertical.
There is obviously some response in the other polarity (more than a
yagi?) but I havent researched this. The square can also be a
rectangle... (Beware of feedpoint Z changes)

You can also feed the in quadrature on two adjacent corners for circular..

I have built about twenty copper-pipe j-poles and I have found that with
five feet or so between the antenna and surroundings, the tuning doesn't
change enough to be annoying.

The copper pipe j-pole can be dropped into a pipe and hoisted into the clear
for VSWR evaluations if you really want to get gnats-assey about it.

Speaking of that, I have found that j-poles usually don't hit 1:1, even
when the low point is mid-band. However, after I get the best match,
I insert a 100 pF capacitor between the coax center pin and the antenna
and "Viola!" I stole that idea from the gamma match.

That situation can be called pure single-point inductive loading. It may not be totally practical, but it is still vital to this discussion.

There is an infinite range of real-life loading coils of various shapes and sizes. Pure single-point inductive loading is the limiting case that marks one end of that range. Any successful theory has GOT to get this case right - and if it can't, it fails.

Regardless of the actual method used, any correct analysis of the whole antenna MUST conclude that, for the limiting case of pure inductive loading, the voltage/current/phase relationships at the loading inductance are the SAME as those predicted by conventional circuit analysis. This limiting case is where the two kinds of analysis come together, and here they MUST agree.

That means a correct analysis for the whole antenna MUST predict zero phase shift in the current (It = I0 cos wt) between the terminals of the loading inductance. This requirement only applies for pure inductance, and only at that single point where the inductor is inserted into the antenna; but for that limiting case the requirement to join up with circuit theory is real, absolute and non-negotiable.

Let's be clear: in this context, "current" is the plain ordinary alternating current that we learned about in school: It = I0 cos wt. It is the simple back-and-forth movement of electrons (charge) past a given point.

Nobody denies that for real-life loading coils there can be a phase shift in the current from end to end, and that it will become larger as the coil becomes longer and skinnier. That isn't the question I'm addressing here. But the question of what happens when the coil shrinks down to become a single-point loading inductance is equally important: it cannot be evaded, and it is a definitive deal-breaker.

It's hard to tell for sure from the avalanche of messages, but Cecil's analysis apparently fails in the limiting case of pure inductance - or rather, he seems to deny that the test is even a valid one.

In principle there is nothing wrong with attempting a traveling-wave analysis for a loaded whip. Done correctly, it will give the right results that join up seamlessly with circuit theory as well.

It's just that Cecil has NOT done it correctly. I think there are
several reasons, and until he corrects them all, his theory will
continue to fail... and he will continue in denial of that.

> . . .

One of the tests the traveling wave analysis must pass is that the results from forward current wave excitation plus the results from reverse current wave excitation must equal the results from excitation by the sum of the two, i.e., the total current. This is required by superposition, whether the network is lumped or distributed.

And analysis based on a distributed model, as Ian says, must converge to the same results as a model with lumped components as the physical sizes of the components get very small.

Analyses of the examples using lumped models with total current have been entirely adequate to explain the observed inductor currents.

The polarization is dependent on the feed point location on the driven element, and the polarization of the drivene element. That's a unique property of full wave loop elements or crossed elements. (Polarity is the wrong word for this application.)

I'm going to have a go with a 3/8 wavelength (for 160M) wire, lifted by a 2M helium balloon during the summer months. The first 40' of wire will be supported vertically by a fibre glass mast then the remaining 156' by the balloon. I have a ground plane in place already and will use a manual tuner at the base to 50 ohm coax, I expect to use this on other bands besides Top band. What is a good type of wire to use, obviously flexible, not too heavy but good copper content, or would electric fence cord (with woven in stainless steel strands) be too lossy? looking for any tips advice etc.

Message-ID: <dvreq9$193e$1@dojima-n0.hi-ho.ne.jp>
Source record: 62438

> Tom, can you clarify on how to take the average height of the pattern?

It is not the average height. It is the average reception power.
Suppose you change the height of RX antenna (preferably together with
TX antenna) by (more than) a half wave length, you'll observe maximum
level Px and minimum level Pn.
So the reception voltages Vx and Vm are sqrt(Px) and sqrt(Pm).
The average voltage Va is then (Vx+Vm)/2. Thus average RX power is Va^2.

> Also, if I keep the TX and RX antenna close, wouldn't that eliminate
> the far-field effects?

It is not a far-field measurement. But the error might not be as
much as 3dB if the distance is such as two to three wave-lengths,
which is sometimes better than the bad average measurement performance
or doing nothing.

Ian White GM3SEK wrote:

To all: Ian is not addressing the issue which is: Can a standing wave current phase measurement be used to tell us anything about the phase shift through a loading coil? The answer is NO! W7EL's phase measurements are flawed. Therefore, they cannot be presented as evidence of anything valid. They certainly cannot be used to prove that a coil is a point inductance.

The question is not whether the two models agree on the low end - they do agree. The question is whether they agree on the high end - they don't and they are not supposed to. The differences I have presented in the two models is where the lumped circuit model fails and the distributed network model is valid.

> There is an infinite range of real-life loading coils of various shapes
> and sizes. Pure single-point inductive loading is the limiting case that
> marks one end of that range. Any successful theory has GOT to get this
> case right - and if it can't, it fails.

Since the distributed network model is a superset of the lumped circuit model, it does get that case right. It also gets the case right at the other end of the range where the lumped circuit model fails. 75m mobile loading coils cannot be validly modeled using the lumped circuit model.

> Regardless of the actual method used, any correct analysis of the whole
> antenna MUST conclude that, for the limiting case of pure inductive
> loading, the voltage/current/phase relationships at the loading
> inductance are the SAME as those predicted by conventional circuit
> analysis. This limiting case is where the two kinds of analysis come
> together, and here they MUST agree.

And they do, no question about that.

> That means a correct analysis for the whole antenna MUST predict zero
> phase shift in the current (It = I0 cos wt) between the terminals of the
> loading inductance.

Here you are allowing your model to dictate reality, not vice versa. A practical antenna is a large structure, usually at least an electrical 1/4 wavelength. There is no such thing as a point inductance in a real world mobile ham antenna.

> Let's be clear: in this context, "current" is the plain ordinary
> alternating current that we learned about in school: It = I0 cos wt. It
> is the simple back-and-forth movement of electrons (charge) past a given
> point.

Let's be clear. That model fails in a transmission line as it does in standing wave antennas. Taking a simple-minded approach to physics is where the air, earth, fire, and water elements came from.

> Nobody denies that for real-life loading coils there can be a phase
> shift in the current from end to end, and that it will become larger as
> the coil becomes longer and skinnier. That isn't the question I'm
> addressing here. But the question of what happens when the coil shrinks
> down to become a single-point loading inductance is equally important:
> it cannot be evaded, and it is a definitive deal-breaker.

In that case, both models give the same answer. But that case doesn't exist in reality in real-world antennas. In reality, the lumped circuit model fails when it is extended to large structures like transmission lines and antennas.

> It's hard to tell for sure from the avalanche of messages, but Cecil's
> analysis apparently fails in the limiting case of pure inductance - or
> rather, he seems to deny that the test is even a valid one.

The distributed network analysis works perfectly in the limiting case since it is a superset of the lumped circuit model. There is absolutely no disagreement between the distributed network analysis and the lumped circuit analysis for point inductors. Anyone who says there is is just attempting to set up a strawman.

It certainly does that within the bounds of the principle of
superposition. But as I earlier pointed out, like two superposed
PSK modem signals, phase information is lost in the superposition.
You used standing wave current phase to try to measure the phase
shift through a coil. Your attempt was futile since the standing
wave current phase doesn't contain any phase information.

> And analysis based on a distributed model, as Ian says, must converge to
> the same results as a model with lumped components as the physical sizes

And it certainly does. But the distributed network model works
for antennas and transmission lines where the lumped circuit model
fails. The lumped circuit model is supposed to fail for transmission
lines and antennas.

> Analyses of the examples using lumped models with total current have
> been entirely adequate to explain the observed inductor currents.

Maybe for you, Roy, but not for me and others. Are the four elements
of earth, air, water, and fire adequate to explain the physical
world to your satisfaction?

> Cecil claims I'm the ONLY one who disagrees with him!

False! Gene Fuller, Tom Donaly, and Roy Lewallen have all made postings that support my side of the argument against yours. That doesn't mean they agree with me 100%. They agree with me on some technical things that are not in dispute except by you.

1. Standing wave current, Func(kz)*Func(wt), is a different thing from traveling wave current, Func(kz +/- wt). The phase of standing wave current contains zero phase information and therefore cannot be used to ascertain anything about phase. Roy's phase measurements were meaningless and his conclusions were flawed.

2. The EZNEC results need to be explained by you guys. When you accused my measurements of being wrong, Roy reported that EZNEC agrees with my measurements. How do you explain that?

3. How do you explain the EZNEC results on my web page at:

http://www.qsl.net/w5dxp/current.htm

All of the arm-waving in the world is not going to make these technical facts go away.

I will be leaving for spring break tomorrow morning and won't be back until Sunday night. It would be nice for you guys to have answered my 12 or so technical questions by then.

Ian White GM3SEK wrote:
> The only thing those people have in common is a desire to get the facts
> right...

I have asked you guys to explain the technical facts behind
about a dozen technical questions of mine. The silence has
been deafening. Many readers of this newsgroup have noticed
the same thing.

Here are the technical facts about the two models. At one end
of the spectrum, we have lumped inductance. At the other end
we have physically huge coils. The crossover point where the
lumped circuit model becomes invalid is about 0.04 wavelength.
A mobile antenna is a lot longer than that. At lengths above,
0.04 wavelength, standing waves have to be taken into account.
The lumped inductance model cannot take standing waves into
account. It assumes instantaneous faster-than-light propagation
of current.

DC|-------------distributed network model valid----------------|

DC|---lumped circuit model valid---| 0.04WL cutoff

Here are the two main technical points:

1. Nothing valid is proven by using standing wave current phase
to measure anything. Gene F. and Tom D. seem to realize that.

2. The taper of the standing wave current through a coil
depends upon where the coil is placed in the standing wave
environment. You guys have looked only at mobile antennas.
Try looking at longer antennas like the one at:

http://www.qsl.net/w5dxp/current.htm

You will find that the current taper through a coil can be
zero, positive, negative, or even reverse phase. The phase
reversal can be considered to be current flowing into both
ends of the coil at the same time.

Please come out of the deep dark lumped circuit cave and
see what the rest of the world is like. You guys have been
seduced by your model. You have assumed the presuppositions
of the model are valid without technical proof.

Here's an analogy:
Ian W. says: I believe water is one of the basic elements and
as proof, I offer a quart of water.

Roy L. says: I believe earth is one of the basic elements and as proof, I offer a bucket of earth.

Tom R. says: I believe fire is one of the basic elements and as proof, I offer this burning torch.

Richard C. says: I believe air is one of the basic elements and as proof, I offer this balloon full of it.

Cecil says: I believe there are over 100 elements and as proof, I offer this periodic chart of those elements.

I will be on spring break until Monday so don't think I have given up on getting the technical facts out there for all to see.

Cecil,

Sorry, Ian had it exactly correct. I cannot speak for Roy or others, but I am quite sure I did not take any "side" in this topic. I believe in lumped circuit models, and I believe in network models. My aim was to try to correct some of the basic math and physics flaws, not to argue over the exact regimes of applicability for lumped and non-lumped models.

If you choose to use my postings as support for your "side", so be it.

At the same time, if proving your "side" includes mobile antennas with 48 foot whips and giant bugcatcher coils working at three times their self-resonant frequency, then please leave me off of your "side".

73,
Gene

I flatly do not accept your notion of a special kind of "standing wave current" that has its own special kind of phase properties.

The current that the loading coil experiences is plain old ordinary alternating current flowing in the wire - the simple movement of electrons back and forth past a point, according to It = I0 cos wt. That is also the current that an RF ammeter reports, and the current that a computer simulation reports too.

Any special kind of current that requires electronic components to behave in some different way from normal is simply not real.

You have a fundamental misconception of what a standing wave of current really is. You repeat all the words about "standing waves", "cos kz", "scientific logic", "laws of physics" etc; but you don't actually let any of it into your mind.

All the questions you ask other people are rooted in your own misconceptions. In other words, the questions are rigged so that they cannot be answered except by agreeing with you. And if someone very sensibly does not answer - why, you "win" that way too. I don't believe you realise how regularly you do this.

Your func(kx)*func(wt) Vs func(kx +/- wt) posting contributed a
good deal of technical accuracy to the discussion and I thank
you for that.

> At the same time, if proving your "side" includes mobile antennas with
> 48 foot whips ... then please leave me off of your "side".

And there's the blind spot. The two antennas are identical except
for the 40 foot extension. The coil doesn't know the extension
is there. Why did the slope of the current taper reverse between
those two configurations? How does the lumped-circuit model explain
more current "flowing" out of the top of the coil than is "flowing"
into the bottom of the coil? It's a simple question but the answer
has been conspicuous by its absence. I will keep asking that question
until someone answers it.

The distributed network analysis handles both of those configurations
in a valid way. Adding 40 feet to an antenna is no problem. The relative
phases of the forward and reflected currents changed - that's all that
happened.

But by adding 40 feet of wire to the antenna, the lumped circuit analysis
falls completely apart. So how do we know it was valid for the 8 foot
antenna where everything is the same except for length? We don't!

Since the lumped circuit analysis falls apart by adding 40 feet to an
antenna, I contend that the lumped circuit analysis fell apart with the
8 foot antenna but you guys don't realize it yet.

I've always suggested cutting teeth on low power, then working your way
up. Mistakes are a lot less dangerous that way. In most cases, I suggest
the MFJ approach. I have one that is now in a emergency backup. My
thoughts on them are that they are certainly not the highest quality,
but they work, and you can always get rid of one to start another ham on
their way.

I've made all my baluns, 4:1 and choke, for my setup. But you raise a
good point, as I'll note below.

>> My rationale is that most new hams these days buy rigs that are
>> all-band, transistorized units.These units are also sensitive to
>> mismatches between antenna and rig. Most new hams are not antenna gurus

Ah, Ed, you have exposed me being shortsighted! I'm a compulsive
homebrewer, and I never considered buying a ready made antenna. The
other approach might be quite different than mine, and yet just as valid.
>
>> So we end up with an antenna that allows the newbie to get on the air,

> yet require more fiddling.

If a person decides to make a trap or even more so a fan dipole, they
will be doing a lot of cutting and trimming and measuring. I've always
thought that for a newbie to get their feet wet, the less of that and
the more on-air experience with adjustments the better.

> But I will grant you this: IF someone decides from the get-go that they

> doublet.

I've made an 88" doublet for field day. It was a very good antenna on
20 and 40 meters, and so-so on 80.(still not too awful bad). I know
someone is going to ask me to define "Very good". In this case, I
received many unsolicited comments on good signal strength on 40 and 20,
had no trouble getting through on first call. On 80 I had to work a good
bit harder.

It is good to get another perspective on this.

Geltlemen,
I have been considering the Wideband Folded Loop (WFL) for a couple of weeks now to use as a secondary antenna when talking with all of the local yocals who are spread out on 40 and 75 and 80 mtrs. I have seen the photographs of the assembled antenna, BUT, no dimentions and by reducing the physicical size of the antenna, I'm guessing the multiple dimentions must be pretty tight to function as a no tuner 1.5 to 30 mHz. Any help would be greatly appreciated. Thanks

Butch KF5DE

I was going to recommend my Oakhills Research qrp wattmeter; it has a
100 milliwatt scale, but it is only rated to 54 mhz. I also looked at
the Bird list of slugs -- they have 100 milliwatt slugs, but not in
the 900 mhz range.

Ian White GM3SEK wrote:
> I flatly do not accept your notion of a special kind of "standing wave
> current" that has its own special kind of phase properties.

We already know that, Ian. Please drag out your dusty math book
and try to understand the difference between the standing wave
current function, func(kx)*func(wt), and the traveling wave
current function, func(kx +/- wt). They are obviously different.
Calling the standing wave current a "current" is something of
a misnomer since it doesn't exhibit the characteristics of a
normal current at all. What are the implications of a "fixed
phase" for a current, i.e. its phasor doesn't rotate?

Do you disagree with Gene's technically accurate posting on the
subject?
****
> Gene Fuller, W4SZ wrote:

>> not really about phase either. It is merely a representation of the periodic
>> sign reversal seen in a cosine function.
****

> The current that the loading coil experiences is plain old ordinary
> alternating current flowing in the wire ...

False! Standing wave current is different from DC, AC, or RF
traveling waves. Please take time out to understand the
implications of a non-rotating phasor for a current. All other
AC currents have rotating phasors but the standing wave current
phasor doesn't rotate all up and down a 1/2WL thin-wire dipole.
That makes it extremely different from any other AC current.

> Any special kind of current that requires electronic components to
> behave in some different way from normal is simply not real.

The forward current and the reflected current are not special. The
superposed standing wave current doesn't behave as normal current at
all. It's phase doesn't change along the entire length of a 1/2WL thin-
wire dipole. I have said this a dozen times and it hasn't yet soaked

in yet so I will continue to repeat it. What does unchanging phase imply about a standing wave current? All other AC currents change phase.

> You have a fundamental misconception of what a standing wave of current
> really is. You repeat all the words about "standing waves", "cos kz",
> "scientific logic", "laws of physics" etc; but you don't actually let
> any of it into your mind.

I am open-minded, Ian, and use the scientific method to correct my mistakes and thus zero in on the technical facts. One of a guru's presuppositions is that he already knows everything. I have no such misconceptions about myself.

> All the questions you ask other people are rooted in your own
> misconceptions. In other words, the questions are rigged so that they
> cannot be answered except by agreeing with you.

No, Ian, my questions are rigged so they cannot be answered except by agreeing with the laws of physics and gurus cannot afford to show their ignorance of the laws of physics. That leaves them between a rock and a hard place as far as answering my questions are concerned. That's the only reason for the "Silence of the Gurus".

I have a ladderline j-pole right outside my attic, in a small tree,
and I lucked out on swr, just following the measurements I found on
the internet diagram of the thing. One trick you might try is to stick
a straight pin into the insulation, touching the longer wire element.
Raise and lower the pin for resonance.

I thought it sounded familiar.

I have not kept in touch the last decade but Bill was a mentor to me.
He did a lot of antenna experimenting, especially on 432 mhz. He is
listed in QRZ.Com, you might send him a snail mail.

As I recall, the article was written during the building of the
antenna. Testing after the article was published did not support the
calculations. Unfortunately you cannot "un publish" a hard copy!

Most of us were still using slide rules & calculators to crunch number
then!

Hi Butch

Are you talking about the terminated folded dipole antenna?

Mr Cebik has a rundown on them at;

http://www.cebik.com/wire/wbfd.html

and says that the antenna is "typically" 90ft long for 80-10m. There is however a non trivial loss at 80m you may want to check on.

If you like "no tuner" also consider Cecils w5dxp's doublet at;

http://www.qsl.net/w5dxp/notuner.htm

That uses sections of 450 ohm feedline that are swicthed in and out of circuit.

Cheers Bob W5/VK2YQA

>looking for any tips advice etc.

Hi Deni,

Make sure you are not violating any civil airspace rules. One
consideration is how do you insure your balloon will not escape?
Another consideration is to make sure the balloon is some distance
away from the end of the wire. Tying the wire to the balloon invites
the high potential at the end of that wire to explode *POP* the
balloon.

It's spring break time and I won't be back until Monday.

On my web page at http://www.qsl.net/w5dxp/current.htm

- is what EZNEC says about a 5.89 MHz, 8' mobile antenna
and what happens to the standing wave current through
the coil when 40' is added to the top of the antenna.
The .EZ files are available for downloading from that
web page. Anyone with a full-featured copy of EZNEC
can duplicate my results.

The *only* change between antennas is the addition of
that 40' of wire. Everything else, including the frequency,
stays the same. (The coil doesn't know that it is supposed
to honor the lumped circuit model and reports the facts
of physics.) The current "flowing" into the bottom of the
coil is 1.29 amps. The current "flowing" out of the
top of the coil is 2.07 amps. Seems that fact alone
is enough to prove that standing wave current doesn't
"flow" in the commonly accepted definition of the word.

Guru gut feelings to the contrary, these results can easily
be proven with real-world measurements by anyone to expend
the time and effort.

The r.r.a.a gurus have four days of peace in which to
figure out a reasonable technical explanation for those
EZNEC results. Enjoy!

> I going to build a 11 element yagi but the problem I'm having is I can't
> find the aluminum rods, I was wondering if I use copper if I will still get
> the same Db gain.

Ya, you'd get the same gain, but the antenna would be pretty damn heavy!

Make your own AL rod like I do: Find AL wire -- about 8-10 gauge will
do. It'll be soft and flexible -- not what you would chose for ant.
elements. Well...

Cut your elements out of the wire -- each about 5-6 inches _longer_ than
you want. For each element, clamp one end in a bench vise and chuck the
other end in a 3/8" or 1/2" electric drill. While pulling back on the
drill, run the drill -- twisting the wire until you have 1 - 1 1/2
twists-per-inch in the element. (Much more than that will make it too
brittle for use.) What you end up with is a nice, stiff, straight rod
suitable for 2M antennas -- and higher in freq.

I made a 6 el. vert 2M beam that I mounted on the fore-boom of my
tri-bander
http://jonz.net/W3DHJ/images/W3DHJ_Tower.jpeg
from
AL conductors that I scrounged from scrap ends of power cable from the
local REA. There were six AL conductors wrapped around a steel core
wire. The AL conductors were about 7/32" in dia.
I got the 15' lengths (useless for them) for free.

Now, if you have large roosting birds in your area, it might require
heftier elements for a horizontal beam than I've described. i do not
have such problems here.

I'm pretty sure you could find large gauge AL ground wire in the
electrical dept. at your local hardware emporium.

Your best hope would be to cascade a small inductance and a larger one.
An alternative is to use a ferrite which looks more like a resistance
than an inductance at high frequencies, though I suppose that's not
really what you are trying to accomplish. (In general it's better to
post more about what you are wanting to do in a more global sense,
because sometimes the best solution is different than what you've
assumed.) Note that an 0.1uF capacitor is very unlikely to look much
like a capacitor above a few MHz, let alone up to 3GHz.

Cheers,
Tom

> phase" for a current, i.e. its phasor doesn't rotate?

This can be improved.

Current is charge movement. DC, traveling waves and standing waves
all are *exactly* charge moving past a given point, and nothing more.

A phasor is not a real thing, but a mathematical abstraction that
relates how the sinusoidal change in current magnitude and direction
relate to a reference periodic cycle in time. Since, in both standing
waves and traveling waves, current at a point, changes magnitude and
sign in exactly the same way (at a point, they are indistinguishable),
they can both be described with phasor notation.

The difference between a traveling wave and a standing wave is how the
phasor representing the current at one point differs from the phasor
representing the current at a neighboring point.

For traveling waves, the phasor of a neighboring point has the same
amplitude but a different phase shift (passes through zero at a
different time).

For standing waves, the phasor of a neighboring point has the same
phase shift, but a different amplitude, unless the neighboring point
is on the other side of a current node. Then it has the opposite phase.

But at any point along both standing waves and traveling waves, there
certainly is a phasor that represents the current at that point.

You need to get past this misconception that standing waves are not
current and are not describable by phasors. I think your concepts are
correct in lots of ways and recently improving, but this is a
recurring snag that keeps detouring your adversaries into straw men
that you offer them on a platter.

Look at www.CoilCraft.com

They have a new series of inductors based on conical shaped coilbase which makes the coil a conical spiral coil. Some types of these are happy all the way up to 40 GHz.

Cheers

Hi Michael,

I tried Google search for salsawaves, and came up with a link to
an OCF "Windom" antenna. But clicking on the link just led to
a sort of highjack web page containing only ad links.

73, Ed

>> phase" for a current, i.e. its phasor doesn't rotate?

The total current ("standing wave current" in Cecil's parlance) certainly does have an associated phase angle, and its phasor certainly does rotate. (By "phase" I mean time phase.) A sinusoidal traveling current wave can be expressed as a phasor whose value is a function of position. When you add a forward traveling wave to a reverse traveling wave, you're adding two phasors. The result is a phasor whose value is the vector sum of those two phasors. This is the total current. It has magnitude and phase like any other phasor, and the same rotational speed as its components. A common manifestation of this is the standing wave pattern along a transmission line.

In a transmission line with two current waves traveling in opposite directions, the phase of the total wave changes with position along the line. Only in the special case where the two waves are equal in amplitude (i.e., when the line is lossless and open or shorted at the end) does the phase of the total current -- the sum of the forward and reverse traveling waves -- turn out to be the same at all points along the line. This can be easily seen from the very well known equations describing wave behavior on transmission lines.

There's no special "standing wave current" that's a "misnomer" or which is a phasor which "doesn't rotate". The total current is indeed a phasor -- its rotation speed is the rotational frequency, 2 * pi * f, just like the traveling wave components from which it can be made by simple addition.

I think the problem Cecil is having with it is that the currents on an antenna behave in a manner that's similar to an open circuited transmission line, which results in the phase angle of the total current -- which can be represented as a phasor -- being the same at every point along the line. The total current isn't current which has "stopped flowing". Like the traveling wave currents it can be split into, it represents the movement -- specifically, the time rate of flow -- of charge. It can be represented by a phasor, which has magnitude and phase like any other. The phase is simply the same at all points along the

line or wire. If the existence of the actual, total current presents problems for an analysis method, the problem lies with the analysis method, not that the total current has the imagined special properties Cecil is claiming.

Once again, any system response such as the voltage across an inductor or the current at any point along an inductor or antenna can be calculated if desired by separately calculating its value resulting from a forward current wave and its value resulting from a reverse current wave. Then the two results can be added together to find the total response. If this sum does not exactly equal the response calculated directly from the total current, then the calculations are being done incorrectly.

There's very little about Cecil's theories that I agree with. He's made many statements which are completely false as I've pointed out numerous times, and his conclusions are largely based on misconceptions and faulty understanding of basic principles.

Hello Bob and tnx for the reply. Check out http://www.rys.nl/wfl.html

this one doesn't look like a dipole and a 7.5 by 1 meter space is all the space it takes up. There are no close up photos of the configuration, and can't tell where feed point is. I'm just full of no information today :o) I did a google search for wideband folded loop antenna, and was presented with this beauty of an antenna, but, like I said, no wiring details and it sells for 400.00!! You just must roll your own.

Butch

Here's one for all our experts and gurus out there:

Consider a 140' dipole up at 40' height. Used on 160-10m

Other scenario is a 50' top loaded vertical, with 4 radials, 70' each, used on 160-20m.

The question is which antenna gives us more radiated energy going out in useful directions?

A fair amount of the dipole energy goes into the ground. Another big chunk goes into cloud warming. That leaves some energy going out at elevations which are useful to us.

The vertical doesn't do much cloud warming. It does have some energy going to ground, but probably less than the dipole. However, it doesn't have nearly as much radiating surface as the dipole has. But, being top loaded, it does tend to get the current node maxed on the available vertical (radiating) surface.

So, holding power input constant, etc, which antenna gives us the more useable rf energy output for hamming on 160-20m?

Limiting oneself to a point measurement is handicapping onself. When
the equation for standing wave current is compared to the equation
for traveling wave current, the real differences are obvious.

> For standing waves, the phasor of a neighboring point has the same phase
> shift, ...

Exactly! Therefore, it cannot be used to measure the phase shift
through a coil or even through a wire.

> But at any point along both standing waves and traveling waves, there
> certainly is a phasor that represents the current at that point.

For the standing wave current it is a phasor that doesn't rotate
all up and down the wire. You have to admit, that's a weird phasor.
It's more akin to DC than anything else.

> You need to get past this misconception that standing waves are not
> current and are not describable by phasors.

Standing waves current is the superposition of two essentially equal
currents traveling in opposite directions. If it was equal DC
currents traveling in opposite directions, what would the net current
be?

Esteemed gentlemen:

I am more of an engineer, inventor rather than scientist, analytic, cosine kind of guy. But I will elevate myself on an occasion to find the root of the problem and proof if needed. Let me try to put the things in perspective, from real life facts, to this "scientwific" debate about the "problem".

1. First I was smacked by the fact that on my 80m Hustler resonator, I re-shrinked, (burned) the insulation on the coil from the bottom up, while operating contest, mobile from Toronto, while spending few last days with my dear mother. I was running about 600W to regular (200W) 80m coil with heavier duty transmitting, during the contest, it was no surprise that it melted the heat shrink tubing covering the turns.
Most people make occasional transmission and do not fry the coil even with more that what it is rated for. On 40m and up I rewound other coils with heavy wire or tubing and extended whips. I would not see the problem there.
I appeared to me strange that the bottom of the coil was fried. Normally I would have expected either "uniform frying" , or perhaps more on the top due to the raising, accumulating heat.
It kind of bothered me, because it was against the conventional "wisdom" or what I knew.

2. When the topic came up, Barry, W9UCW, knew about the effect and done some real life, real antennas, real RF ammeters measurements and found out that indeed, the RF current at both ends of a typical loading coil (quarter wave resonant, coil loaded vertical antenna) is different. He described it, offered some photos and data about the measurements.
Please see http://www.k3bu.us/loadingcoils.htm
In his example he showed that 40m typical, loaded vertical, had about 40% less current at the top than at the bottom. That made me happy, it made

sense and explained what was happening with my Hustler. So I got some insight into the workings of the loaded, shortened radiator or element. Reality agreed with engineering measurements, experiment, that anyone can reproduce and verify.
The conclusion was:
"There IS a drop, difference in RF current across the antenna loading coil."
The significance (to me anyway): Efficiency of the radiator, antenna is proportional to the area under the (cosine) curve of the current distribution across the radiator. The loading coil, as it turned out, had significant contribution to that current distribution that it got my attention. Knowing the effect, we can play with different position of the loading coil within the radiator and experiment with various ways of top loading, to maximize the current flow within the desired portion of the radiator, to maximize the area under the cosine current curve - to maximize the efficiency under given restriction for the particular antenna design. Here comes the compromise between loading inductance (coil, stub) vs. capacitive hat (T, L, disk) loading.
So in the typical loaded (mobile or shortened) vertical we are trying to maximize the efficiency and it is important to know what is the current distribution across the radiator. If the coil has a drop in order of 40 - 60% as it appears to be, than that is significant to me to take it into the account. Knowing how to apply this effect will allow me to optimize, maximize the antenna performance.
So far with me? If not, ask the questions or tell me where I am wrong.

3. Then Tom, W8JI and his followers, with some "backing" from literature (plenty are wrong), some experiments, modeling, came to "prove" that it can't be so. His conclusion: "The current in the antenna loading coil is the same at both ends". Then the "fight" and controversy started.
It appears to me that JI camp is coming from the theoretical end of it, applying laws of physics and theories that do not apply to the case in question.

4. Cecil, W5DXP came to the rescue by explaining and modeling the case and supporting K3BU/W9UCW case and reality. We were happy to have that support, shining more light on the scientific side of the effect and effort to correlate the crude observations, real life measurements with theory, modeling and analytical end of it.

5. Not so fast. JI camp vehemently defended their "equal current" case, using examples, modeling, tailored to support their claims, for some reason ignoring the reality, measurements, experiments done to set the coil in the spot where current can be, and is the same (no argument with that).

6. Cecil, W5DXP started to dig deeper into the effect, showed that if we model the coil as a loading stub, EZNEC shows the difference in the current. When modeled as a solenoid, it also shows the difference. When the loading is inserted as a simple L (zero physical size) inductance, then EZNEC "proves" that current is the same. So for the same inductance, of different physical model (same electrical) properties EZNEC "proves" that each camp is "right". The only problem is, which case represents the reality and should

be taken seriously.
To prove the point further, Cecil showed that positioning the coil in various position within the radiator, one can aggravate the difference in current at the ends from one extreme of being equal, to the other extreme of being max at one end and zero at the other, depending on the size of inductor, position within the antenna and frequency applied. To me it makes sense, explains the "workings" of the effect, puts some numbers on it and shows how to model it, apply it and UNDERSTAND it. That's the way IT IS - the reality. Anyone can verify it, do the experiment (otherwise, please prove us wrong and where) and now - even model it in EZNEC when using proper definition of the model coil (solenoid or loading stub of equivalent inductance).

7. No, Cecil, didn't do the stupid mobile antenna trick with quarter wave extension. He used it as an example to show how one can play with the model to see the different situations and show that current can be from equal to extreme (max to zero) across the loading coil. In the EZNEC you can vary the position of the coil (solenoid or stub), length of the radiator and frequency to see the current value and distribution across the coil/radiator. Thanks to Cecil (and "solenoid" Roy), we have now improved way of modeling the effect, understanding it and better way of applying to antenna design. Thanks Cecil, you have golden patience, persistency and are a great defender of the TRUTH!

8. But Noooo! W8JI camp and non-believers can not accept that (reality). They cling to the "explanations" why it can't be so, because of "purple electrons, phasor eating extremists" would not allow it to be so. They are dancing around the facts and examples of why it is not so, not answering latest W5DXP questions, but the main thing - not verifying the reality with proper experiment or measurement (not important?). They are trying to prove that reality isn't, Tesla and others are fools, because of what??? Pride? Can't be wrong? Emperor has equal current clothes?

9. If anyone is trying to argue the case that (eventually) current is (or close to) equal, by arguing that sticking the coil at the base or where there is virtually no difference because of the position of the coil and current distribution in the radiator, forget it. We are not arguing that (and we agree with THAT special case). We are arguing with general statement, as displayed on W8JI pages and argued by the "guru followers" that the "RF current across the antenna loading coil IS (always) the same" (or close, losses, bla, bla) in the TYPICAL loaded or mobile antenna. NOT in the special case where it indeed can be. THAT WAS the subject of the discussion and problem that started all of this. Not current in ANY coil, in ANY circuit. We are not arguing minute diffrences due to radiation, resistance, capacitance surface effect, etc., we are arguing the difference of a 40 - 60 % of current drop across a typical loading coil in a typical mobile or loaded antenna.

10. According W8JI camp, looking at the quarter wave loaded whip, the current goes up the radiator according to cosine curve, then is the same across the coil, then tapers to zero at the tip in the triangular shape

(should be the rest of the cosine curve, but close enough approximation). We are talking about typical loaded resonant quarter wave ant, (not any coil in any circuit).

11. According to K3BU camp, the same happens as above, except the current across the coil drops at the top of the coil to typical 60 - 40 % (for 80 - 40m) and then tapers to zero at the tip. Again, (I hope no dispute over this) efficiency of the antenna is proportional to the area under the current distribution curve across the radiator with the loading coil. So according to W8JI camp, the loaded radiator would have better efficiency than it really has, by about 60 - 40 % of the above the coil current curve area.

12. To me this is significant and worth exploring, because knowing the effect will allow me to better design, model and optimize antenna systems with loaded elements. The difference in the amount of current in the remaining portion of the antenna is not negligible and the effect will magnify itself when designing multielement loaded antennas. If the model shows wrong amounts and distribution of the current, the results will be off and real antenna will not perform as modeled. Those ARE the currents we consider in modeling, show their distribution off and calculate the antenna parameters with (right Roy?) So, to some the whole argument may be insignificant, to me it is, it should be known, properly considered and applied in the antenna modeling and design, otherwise it could cause inaccuracies and wrong results.

13. So where are we now? We have the effect, we have the measurements, we have explanation, we have the recipe how to model it properly, we have some results. Others can duplicate and verify it. (And answer the frickin Cecil's questions!!!!)
Then we have W8JI camp that insists that it ain't so, twisting and dancing trying to "prove" that it just can't be so. Using "arguments" of their own, often contradicting themselves (ooops) that it just couldn't be, because, because, because....
Well, IT IS, if your egos like it or not. It is almost amusing to read the thread and arguments trying to defy the reality by "scinetwific proof". Cecil's arguments and question are selectively ignored and not argued, while new twists and detours are brought in.

14. So if the W8JI camp can not swallow reality, so be it, eventually live with giant egg on the face. I am extremely grateful to W9UCW, W5DXP and others in "our" camp for their contribution to the discussion, explanations, shedding their light and wisdom on the subject (and patience, and persistence). I have learned more about the loaded antennas and will use it especially in the design of receiving arrays for the new Tesla Radioclub salt water marsh 175 acre antenna farm (www.TeslaRadio.org)

15. One more time, friendly advise to Tom, W8JI: If you strongly defend posting the truth on Internet, live by it. It takes big guy to admit being wrong, learn and give credit where it is due! Ridiculing someone being wrong, especially when he is right is not in the spirit of ham radio and decency. Playing guru, engineer and pontificating might go well on TV show

but in real life there are consequences. Arguing on a wrong side, then after realizing being wrong, going QRT for a while and then emerging as a guru and portraying the subject as own invention, without giving credit to "arguer" smells with plagiarism. I am saying this here, because I was few times publicly ridiculed by Tom while being right, as he later confirmed by eventually propagating "my gospel" as his own. We should be engaging in civil discussions and arguing about the topics, so we can all learn and be better. If this whole exercise will contribute to that, then it was worth it. If not, then keep on truckin'.

16. To the rest of the readers, I though that by now we all would be on the same "camp reality", but looks like there is still a rocky road ahead. I think we will get better results and go to radio heaven for sticking to the "current in loading coils" truth. I promised comprehensive article on the subject, but life keeps throwing more important problems in my path, but I will try hard to do it soon. We shall summarize our camp's wisdom and hope for convincing case for the unbelievers.

I tried to portray the picture of reality and significance of the subject in hope of bringing the refusniks aboard. You all can be the judges of what good it was.

We could look at some other "gospels" at Tom's web site, but that is another story when subject comes up. (All in the name of dispelling the myths and old waives tales as Tom likes to do.) I don't like to pick a fight, but I don't stand by when there is a significant myth or wrongo being propagated, I will defend the truth with my last breath (if it is worth it :-)

I think 'nuf said, we all did our best to conway the reality, the readers can draw their own conclusions and if important, verify this and that to see who is RIGHT and if they can benefit from the findings. Good luck and I rest my "piece of coil".

I was just making sure we were using the same definitions for things
like current and phasors. You are jumping ahead. :-)

>> For standing waves, the phasor of a neighboring point has the same
>> phase shift, ...
>
>
> Exactly! Therefore, it cannot be used to measure the phase shift
> through a coil or even through a wire.

I agree, unless you use phase measurement to hunt for the location of
the current nodes that have moved as a result of adding the coil.
Finding a phase reversal at opposite ends of the coil, for instance,
implies that an odd number of nodes reside in the coil.

>> But at any point along both standing waves and traveling waves, there
>> certainly is a phasor that represents the current at that point.
>
> For the standing wave current it is a phasor that doesn't rotate
> all up and down the wire.

A phasor rotates at the reference frequency, and with a phase angle
that represents the angular difference between the value in question
and the reference cycle. Pick a point on the conductor, and if it
carries either a standing or traveling wave (or any combination of
traveling waves at the reference frequency), the current at that point
is describable as a phasor (having a specific magnitude, and a
specific phase with respect to the reference cycle).

> You have to admit, that's a weird phasor.
> It's more akin to DC than anything else.

This is your mental block. A phasor describes the activity at a
point, not whether that activity is a result of an energy wave moving

past in one direction, the other, or some combination of those.

>> You need to get past this misconception that standing waves are not
>> current and are not describable by phasors.
>
>
> Standing waves current is the superposition of two essentially equal
> currents traveling in opposite directions.

No. Currents do not travel. Current is the movement of charge past a point. Cyclic current is a sloshing back and forth of charge at some frequency. If you want to picture that process with respect to time, you can refer to it as a cycle or wave, but it is a wave on a scope trace or time graph, not a physical wave of something moving along a wire. The physical wave is charge slushing back and forth along the wire.

Both traveling energy waves and combinations of them (standing waves, for example) involve energy traveling in various directions, but the current does not travel. It occurs at a point, as charge moves back and forth past that point. When you can separate the concept of current from the concept of energy waves, you might see this snap into focus.

I am not trying to be the guru, here. My earlier posts confused these same concepts, when I mentioned current waves traveling in various directions. I was mistaken, and have seen my error, and am trying to get you to see it, also. I should have been speaking of charge waves that produce current. Correct thinking requires correct speaking. You cannot be sloppy with words and have (let alone express) clear thoughts. This thread has done a lot to help me clear up both my words and thoughts, and I thank you for that. I am not absolutely sure that I have eliminated all mistakes from this way of talking about the process under discussion, so I may have to make some more corrections. That is the reason I am watching this thread.

> If it was equal DC currents traveling in opposite directions,
> what would the net current be?

Their algebraic sum, same as for non equal currents. Same for any combination of currents that result from charge being shoved back and forth by passing energy waves. Instantaneously the current is the algebraic sum of all components passing through that point. If the components are AC at the same frequency, the sum will be some resultant instantaneous current that varies with that same frequency.

I think I agree with just about every conclusion you are making about treating coils as slow wave transmission lines. The nits I am picking is in the language you are using to describe these effects to justify those conclusions. I think terminology is at the root of most of the disagreements in this thread.

Roy Lewallen wrote:
> The total current ("standing wave current" in Cecil's parlance)
> certainly does have an associated phase angle, and its phasor certainly
> does rotate.

The standing wave current phasor in a 1/2WL thin-wire dipole *DOES
NOT ROTATE* and is fixed *CONSTANT AT ZERO DEGREES*. Please reference
Figure 14-2 in Kraus' "Antennas for All Applications", 3rd edition,
page 464. It shows *ZERO* phase shift in the standing wave current
from tip to tip in the 1/2WL thin-wire antenna. It is obvious from
the standing wave current equation that the phase angle doesn't
change with position.

This one misconception is what has got you and Tom totally confused.
Please correct your misconception. It's the forward current phasor
and reflected current phasor that does the rotating. Since they are
rotating in opposite directions, the phasor sum of those two
phasors is essentially *CONSTANTLY ZERO ACCORDING TO Kraus*.

> (By "phase" I mean time phase.) A sinusoidal traveling

> pattern along a transmission line.

Roy, those two phasors that get added are *ROTATING IN OPPOSITE
DIRECTIONS!* The phase of the sum of those two phasors is *CONSTANT*!
If you had read: http://www.qsl.net/w5dxp/current.htm you would
know that already. That's the mistake that you and Tom have been
making for years and you are still making the same arrogant mistake.

Don't you believe what Gene Fuller posted?
****

No, it does NOT! at least not by more than a few degrees. In
Func(kx)*Func(wt), the phase is divorced from position on the line.
If you don't believe me, would you believe EZNEC? When I told Tom
that I had measured unchanging phase all along a dipole, you said
EZNEC shows the same thing.

> Only in the special case where the two waves are equal in
> amplitude (i.e., when the line is lossless and open or shorted at the
> end) does the phase of the total current -- the sum of the forward and
> reverse traveling waves -- turn out to be the same at all points along
> the line. This can be easily seen from the very well known equations
> describing wave behavior on transmission lines.

That's true. Now take a look at Kraus' diagram referenced above. Kraus
assumes the forward current and the reflected current on a 1/2WL thin-
wire dipole are *EQUAL* in magnitude. The same assumption is approximately
true for a 75m mobile antenna.

> There's no special "standing wave current" that's a "misnomer" or which
> is a phasor which "doesn't rotate". The total current is indeed a phasor
> -- its rotation speed is the rotational frequency, 2 * pi * f, just like
> the traveling wave components from which it can be made by simple addition.

Sorry, Roy, you are just wrong on that one. Please dust off your old
math book. Func(kx)*Func(wt) DOESN'T ROTATE with 'x'. For any 'x', it
just stands there exchanging energy between the E-field and H-field.

> I think the problem Cecil is having ...

Methinks you had better do something about that beam in your own eye
rather than worry about the speck in mine.

>... with it is that the currents on an
> antenna behave in a manner that's similar to an open circuited
> transmission line, which results in the phase angle of the total current
> -- which can be represented as a phasor -- being the same at every point
> along the line.

That's not a problem. That's exactly what Kraus and EZNEC both say.
You are the one having a problem with it and you really need to correct
your misconceptions before the discussion can progress.

Or another mistake on my part. I am more interested in clearing up the later. As far as what is happening in a loading coil, I am in general agreement with you and EZNEC. It is only the details of the discussion of the cause that I am still tripping over.

It may be you or I may have an untied shoe.

If you can answer which is best: Mac truck or Corvette?
We can answer your question.

It depends on lot of things, what you want to do with it (who to communicate with, where, when, what band) etc.
You need to consider propagation modes and nuances
Know the antenna patterns for particular band
Antennas are a fascinating subject and there is a lot of information in the literature and worth studying if one is serious about operating on the bands.
Knowing that, one could do good job in selecting or designing the antennas for particular task.

John, I didn't say the amplitude couldn't be used to determine
phase. The current nodes are associated wiht amplitudes, not phase.

Yes, but the standing wave phasor doesn't change phase with position.
The traveling wave phasors change phase with position. That's a big
difference.

In any case, Jim, oops, I mean John, here's the IEEE Dictionary's
definition of current.

"current - The flow of electrons within a wire or a circuit:
measured in ampheres." And no, there is no definition for
"current flow" in the IEEE Dictionary.

"Current flow" and "power flow" are commonly used terms to
signify "charge movement" and "energy movement". Objecting
to the use of the words "current flow" is really picking at
infinitessimal nits.

A coil itself isn't a slow wave transmission line. In conjunction with shunt C, it can be analyzed as a transmission line, but only in conjunction with shunt C. Remove the shunt C and it ceases looking like a transmission line. The earlier example of the modification to Cecil's EZNEC model illustrated this -- when the ground (the other side of the shunt capacitor) was removed, the current drop across the coil disappeared.

As far as considering a coil itself as a "slow wave structure", Ramo and Whinnery treat this subject. It's in the chapter on waveguides, and they explain how a helix can operate as a slow wave waveguide structure. To operate in this fashion requires that TM and TE modes be supported inside the structure which in turn requires a coil diameter which is a large part of a wavelength. Axial mode helix antennas, for example, operate in this mode. Coils of the dimensions of loading coils in mobile antennas are orders of magnitude too small to support the TM and TE modes required for slow wave propagation.

A 75m bugcatcher has its own shunt C called "distributed capacitance".
It's what causes the self-resonant frequency of my 75m bugcatcher coil
to be only 60% higher than the 4 MHz operating frequency.

> Remove the shunt C and it ceases looking like a transmission line.

That's true *only* for a lumped-circuit inductance. It is NOT true
for a 75m bugcatcher which has it very own distributed capacitance
built in. It is *IMPOSSIBLE* to remove the distributed shunt
capacitance from a 75m bugcatcher coil.

> The earlier example of the modification to Cecil's
> EZNEC model illustrated this -- when the ground (the other side of the

That may be true but please tell us how to remove the ground from a
75m mobile bugcatcher mobile antenna installation.

> Coils of the dimensions of loading coils in mobile
> antennas are orders of magnitude too small to support the TM and TE
> modes required for slow wave propagation.

Sorry Roy, Dr. Corum disagrees with your statement. You really should
read the details of the Dr. Corum web page references that I posted.

His test for the validity of his helix equations is:

5*N*D^2/lamda(0) <= 1 where N is number of turns, D is diameter,
and lamda(0) is the self-resonant frequency.

That value for my 75m bugcatcher coil is 0.4 so his equation for
velocity factor is valid. The velocity factor for my 75m bugcatcher
coil calculates out to be 0.0175. Now that's what I call a "slow
wave" coil.

But I have offered all these references weeks ago. Are you too
arrogant to even have read them? (Another rhetorical question)

Hi Butch

Okay it looks like a T2FD that has been folded over. Usually they have a load resistor (600 ohms maybe) and a toroid matching transformer at the feedpoint. (The antenna is close to 600 ohms without the transformer) Cebik explains how much loss this system incurs so you can make some judgements from that. The smaller capture area than a "real" T2FD may mean another 3-6dB or so of loss.

You might like also to look at a magloop generally. ie a loop antenna with a tuning cap at one location. I have seen these described as working well over a 2:1 freq range (eg 80 and 40m) and a few quoting 3:1. You usually need to remote tune them though with something like a srewdriver motor. As mentioned in the advert one of their claims to fame is lower received noise and with the tuning less off frequency interference issues.

Whats your application, what bands do you want to cover and what space do you have?

Bob

3331. Multiband Dipole Angles

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-22 22:17:19 UTC
From: Troy Majors <leica3f@earthlink.net>
Message-ID: <P1kUf.9143$sL2.6368@newsread2.news.atl.earthlink.net>
Source record: 62541

What effect will the following have:

both legs of the multiband dipole 60 to 65 feet up in the air cannot be in a straight line, but one leg must vary from a true north-south diple to the northeast at about a 35-40 degree angle from the other leg. Also, both legs slant downward in a slight inverted-V configuration, probably about 20-25 degrees. The feed line will come straight down at a 90 degree angle from the dipole legs, but will then split the difference in its horizontal move along the ground to the house. How much do I lose from all this compared to a dipole with both legs straight in line, and the feedline 90 degrees from the dipole both vertically and horizontally?

All this is driven by the size of the lot, the placement of the trees in the back and front yards, the direction and density of the various limbs off the trees, and the level of my skill with a slingshot. I have the pilot ropes in place but have not raised the antenna yet. Any advice before I commit to this configuration?

Thanks,
Troy

3332. Radials

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-22 22:42:47 UTC
From: hasan schiers <schiers@netins.net>
Message-ID: <dvsjt8dis1@news.netins.net>
Source record: 62542

I'm having trouble resolving the values produced by Reg's "Radials2" program and the excellent section in ON4UN's Low Band DX'ing, 4th Edition.

Reg's work seems to be saying that placing radials on the ground shorten their resonant point such that having radials the recommended 1/4 wave physical length is not necessary, or even desirable. When I played with the program, the losses reported by Reg's program with radials as short as 10 or 20 feet were quite low, with sufficient number of them. Is this overly optimistic? (1/4 wave vertical)

Here are the points of departure that I'm having trouble "resolving".

Quoting from Chapter 9, section 10, Part 2.1.2:

"A 1/4 wave wire that is resonant above ground, is no longer resonant on or near the ground. Typically for a wire on the ground, the physical length for 1/4 wave resonance will be approximately 0.14 wavelength." (the exact length depending on ground quality)" This seems to agree at least somewhat, with Reg's assumptions in his program.

However, when we get to section 2.2.3 (again in Chapter 9, section 10), John asserts:

"As soon as you use a larger number of equally spread radials, the RESONANCE EFFECT DISAPPEARS, and the radials form a disk, which becomes a screen with NO resonance characteristics. In this case, we no longer talk about length of radials, but about the diameter of a disk hiding the lossy ground from antennas." Unless I misunderstood Reg's program, it seems to maintain the idea of velocity factor/resonance in radials, no matter how many there are.

John Devoldre (ON4UN), then goes on to describe the early work by Brown, Lewis and Epstein, as well as the exquisite study done by N7CL where he developed a formula for optimizing radial systems based on amount of available wire.

The magic number for efficiency in a radial field appears to be 0.015 wavelength tip to tip spacing at the radial perimeter. Fewer wires and larger spacing degrade the radial field performance. More wires and closer spacing do not improve performance significantly. The formula looks like this:

N = ((2*PI*L)^0.5)/A

Where N = the number of radials, L = the amount of available wire and A = the tip to tip distance (1.3 meters for the 80m band)

For 500 meters of available wire, the most efficient use of the wire is:

N = ((2*PI*500)^.5)/1.3 or 43 radials.

The length of the radials is 500 meters/43 or 11.6 meters long. This arrangement maintains the .015 wavelength tip to tip separation at the perimeter.
==========

Now, the case for perfection:

Section 2.1.3.2

"From these almost 70 year old studies (BLE), we can conclude that 60 1/4 wave long radials is a cost-effective OPTIMAL, solution for amateur purposes. The following rule was EXPERIMENTALLY derived by N7CL and seems to be very sound and easy one to follow."

"Put radials down in such a way that the distance between their tips is not more than 0.015 wavelength. This is 1.3 meters for 80 meters and 2.5 meters for 160 meters." The circumference of a circle with a radius of 1/4 wavelength is 2*PI*0.25 = 1.57 wavelength. At a spacing of 0.015 wavelength at the tips, this circumference can accommodate 1.57/0.015 = 104 radials. With this configuration you are within 0.1 dB of maximum gain over average to good ground. If you space the tips 0.03 wavelength, you will lose about 0.5 dB."

"In general, the number that N7CL came by experimentally, closely follow those from Brown, Lewis and Epstein."
==========

Now, Reg has in the past, objected to the BLE data because they didn't measure ground conditions. This issue is dealt with by N7CL, but it is too rigorous for me to type into this message. Suffice it to say, the formula appears to hold NO MATTER WHAT the ground conditions are like....i.e., the best use of an available length of radial wire (several hundred meters), is the formula listed above, and there is no resonance effect, no velocity factor effect (that is meaningful)...

This seems to challenge, at its core, Reg's assumptions for his program on radials. Or am I missing something?

There is no doubt that there is some agreement with Reg, but there are several points of departure, that strangely enough lead us back to B,L and E as being the most authoritative and experimentally verified data. That is not to say the B,L & E data is very well explained....but...with the addition of N7CL's work, radials are now "manageable for the masses", and the two studies appear to agree.

Anyway, I found this stuff a lot more interesting than the endless bickering about magical properties of phasors, lumped constant vs. distributed networks, and when is an inductor an inductance, ad nauseum, so I thought I throw this out and see if anyone else finds it interesting and would like to comment.

What I'm looking for is max low angle radiation comparison of the two.

3334. Current through coils - BFD

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-22 23:14:58 UTC
From: Richard Clark <kb7qhc@comcast.net>
Message-ID: <mu7322hcinluakhvtib9t6l9a9104de8jj@4ax.com>
Source record: 62545

Well, let's start with Yuri's emphasized and cogent assertion:
"The current in a typical loading coil in the shortened antennas
drops across the coil roughly corresponding to the segment of the
radiator it replaces. "

We have:
1. A shortened antenna;
2. a loading coil;
3. a current drop across the loading coil;
4. a 1:1 relation between loading coil and
"the segment of the radiator it replaces."

What follows is a weave of contradictions, shortfalls and analysis
that whacks the funny bone with a slide rule.

On Sun, 19 Mar 2006 15:39:23 -0500, "Yuri Blanarovich"
<K3BU@optonline.net> wrote:
>The case was of electrical quarter wave vertical radiator (as loaded mobile
>antenna) and that the current is distributed, varying across the coil as I
>have experienced, W9UCW has measured and Cecil has explained.

So far, nothing has changed to the assertion from Yuri's page at the
top of this post. However, leaning on Cecil for support is....

Well, that can, and did, go anywhere - you need to bring your own
vaseline and don't expect a kiss afterwards.

****

What about point 4 above:

On Thu, 16 Mar 2006 08:56:19 GMT, Cecil Moore <mycall@arrl.net> wrote:
>> When the speculation is that the coil presents a 1:1 replacement for
>> the delay of the "missing" segment of the resonant antenna, then this
>> premise stumbles at the starting blocks.
>
>Nobody said anything about a 1:1 replacement. That was just
>somebody's strawman.

Well, now we have a name put to the strawman.

But wait! Is this quoted sneer beyond redemption? True to the
ability to believe three impossible things before brunch, we can find
contradictions within the encompass of one skull:
"number of degrees occupied by the coil in the above examples is
estimated to be ~60 degrees since the self-resonant frequency of
the coil is approximately 9 MHz. A very rough estimate of the

electrical length of the coil can be obtained using an arc-cosine
function on the standing wave current amplitudes."

Of course his vulgar usage of language that announces brilliant
logical conclusions is fraught with problems.

****

What about point 3 above:

"is it possible to have 1.29 amps of current "flowing" into the
bottom of the coil and 2.068 amps "flowing" out of the top? Of
course not!"

The "logic" of this rather emphatic assertion is what most would take
as a roundhouse to the chin of cordiality. Cecil, in his usual style
has sacrificed results to teach a lesson. Unfortunately this is part
and parcel to his rather frequent impeachment of his own references.
"A poor carpenter blames his glue-gun."

Yuri, with testimony like this, you have a trusted friend by
comparison in Tom.

****

What about point 1 above:

"78" base mast (including spring and mount) with a 38" top whip
(including 12" of alum. tubing for adjustment)"

HOWEVER, the same source also states:

"92" mast"

with absolutely no discussion of the stinger shown in the photograph.
This is a pretty poor specification given the calories expended in
emotionally developed "theories."

For the purpose of further discussion, it appears the "intent" of the
specification has two sections, each 92" tall.

****

What about point 2 above:

"using a HI-Q coil (openwound airdux, 2 1/2"d)" with 60 turns

This, too, is a pretty poor specification because I could only guess
at the turns count, and to me, the meters look like standard 3ï¿½" panel
mounts which would make this a 4" coil instead.

For the purpose of further discussion, it appears the "intent" of the
specification is a 60 turn coil of 2ï¿½" diameter.

****

Beyond one simple inclusion:

"radial field (60)"

Nothing more is offered in way of specifying the radials. This, like the examination of the coil, is fraught with issues.

For the purpose of further discussion, it appears the "intent" of the photograph supplied with boards in the grass, that this field's radius is 92"

****

A search of Yuri's page reveals no frequency specification, simply band assignments.

For the purpose of further discussion, it appears the "intent" of the article is with a resonant system built from the presumptions offered above and facts gleaned from the article, and this frequency is established as:

7.225 MHz

****

EZNEC reports that the current just beneath the load:

1.0044 @ -0.91ï¿½
and at the top of the load:
.80128 @ -1.08ï¿½

Best gain report is:

-1.37dBi @ 28ï¿½

****

There are further complications. The report at Yuri's page also mixes in discussion of currents with the coil/meters at various positions (unspecified except in general) with the notable inclusion of:

"(with hat) and reresonating"

which is a leap of faith in coming to terms with just one issue.

In other words:
1. Is the hat always present;
2. what size is the hat;
3. how is reresonating accomplished.

****

As a variation, I simply tossed the coil, replaced it with a straight wire section, and added 10 distributed loads of 69ï¿½H.

This last was a bear to wrestle into resonance by adjustment. Along the way there were reports of negative resistances until I passed

through them to find the lowest practical reactance (for me, that is
1/10th of the real resistance).

The currents across the 10 loads showed a wild variation of up to 10:1
however, the current in the segment before the first loaded segment

1.1802 -0.21ï¿½
and the current in the segment after the last loaded segment
.99314 @ 179.79ï¿½
is roughly similar to the coil model above.

Best gain response of:

-1.02dBi @ 30ï¿½

****

As a further variation, I tossed out 9 of the 10 loads, and set the
remaining load at 16.5ï¿½H

The current into/out of this load is barely remarkable against the
general decline of current readings leading up to or away from it.

Best gain response of:

-1.65dBi @ 28ï¿½

****

Net result, greatest variation in antenna gain = 0.63dBi

Average variation in antenna gain = 0.315dBi imperceptible by
definition.

Hi - Steve,
Yes - that is correct.
If the quad is a diamond shape for example, you could feed it either from the bottom "V" or the side "V". What is the polarity at each feed point?
Also - if the antenna is a square, you can feed it from the middle of the bottom or the middle of the side: again what is the polarity vs. the feed point?

Sorry Richard, Since you deliberately distorted what Yuri said,
everything else you say is irrelevant. What is it about "roughly"
that you don't understand? "Roughly" could mean +/- 50% accuracy.

Why do you guys feel you have to distort everything in order to
win a technical argument? If you are so technically correct, just
give us the technical facts and skip the deliberate distortions.

The vertical, should have a far better low angle performance, although
four radials is probably inadequate to minimize ground absorbtion.

The inclusion of a loading coil does little or nothing to effect the
radiation
efficiency.

If you can measure phase, you can see that it is opposite on opposite
sides of a node. There is a 180 degree phase shift each time the
measurement passes over a node. Do you disagree?

>> A phasor rotates at the reference frequency, and with a phase angle

That's exactly the difference. But if you measure a single point, you
can't tell whether you are measuring a point on a traveling wave or a
standing wave. Agree?

>> No. Currents do not travel. Current is the movement of charge past a

Afraid so. The concept of current already includes the concept of
flow. Current is charge flow. Current flow is charge flow flow??

Must comment- that the answer is "MAYBE"! It depends on what is
UNDER that roof! If you have metal flashing (near vents, furnace
pipeing), or insulation with a "VAPOR BARRIER" usually, aluminium
foil backed, it may affect your ability to xmit a signal , and in
the case of the latter, might make a great "FARIDAY SHIELD" (signal
proof room)! And this would apply to comercial antennas as well!
Tho, the wood in a roof, and the roofing material should be
generally passive to even UHF, the other materials might be
a problem. Dont give up hope, as have friend witha antenna
(quad), on 6 meters, and 2 meters, in an attic dormer, if it had
been insulated correctly, would have been relatively RF Proof!
Might want to examine it before betting too complex! Jim -NN7K

Not at all? It seems to me that any real, physical inductor must have some lumped properties and some transmission line properties, and it is the balance of these that must be considered in any particular case to decide which analysis is the more accurate way to deal with it in a circuit. Solenoidal air core inductors have a lot of transmission line properties if the frequency is high enough. If this were not so, they would look exactly like fixed capacitors above self resonance, instead of having multiple impedance peaks and valleys.

> In conjunction with
> shunt C, it can be analyzed as a transmission line, but only in
> conjunction with shunt C.

But any real, physical inductor has shunt capacitance to its surroundings. So if you neglect this without considering whether or not this is reasonable, you are going to be blindsided by its effects, eventually.

> Remove the shunt C and it ceases looking like
> a transmission line.

How do I remove the shunt C of an inductor? With an active guarding scheme?

> The earlier example of the modification to Cecil's
> EZNEC model illustrated this -- when the ground (the other side of the
> shunt capacitor) was removed, the current drop across the coil disappeared.

So whether or not this coil is acting as a slow wave transmission line in addition to being inductive depends on the surrounding fields and connections? I have no trouble with that.

I'll have to take your word for this limitation. But it seems to me
that the length of the coil in relation to the wavelength and even the
length of the conductor the coils is made of are important, also.

Source record: 62555

(Yawn) So, I have this system where there's a wave in each direction and they are identical amplitudes so that there is zero loss to radiation or thermal dissipation. And in this system there is a series coil through which the waves pass, and the current at each end of the coil is different amplitude. That means that the coulombs/second passing a point at one end of the coil is different than the coulombs/second passing the other end of the coil. The currents can be in phase or counter-phase. In fact, if the phases of the currents at the two ends of the coil were not the same, then even equal-amplitude currents at each end would imply that, except at certain instants of time, there are differing coulombs/second passing the points at either end of the coil.

What happens to that imbalance in charge? Where does it go? What do we call something that behaves that way? What's so freakin' special about that?

Cheers,
Tom

That is where we disagree. While it has been years, as I recall you claimed the electrical degrees the inductor replaced caused the slope across the inductor.

The point I (and others) tried to make was that in a small inductor current was essentially equal at both ends of the coil, and any change had to be caused by capacitance from the coil to the outside world that was large compared to the termination impedance at the top of the inductor.

It really is a shame you flew off the handle so fast and we didn't talk through the problem. That's why misunderstandings start and drag on for years.

This has become a "let's get him" thing instead of "let's figure out how it works".

> So in the typical loaded (mobile or shortened) vertical we are trying to
> maximize the efficiency and it is important to know what is the current

> maximize the antenna performance.

If you look at the measurements at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

you'll see for a given antenna structure, I can change the current distrution all around. The current in a small loading coil of reasonable form factor is essentially uniform at both ends of the inductor.

This is because the inductor does not replace a certain "electrical degrees" and have a cosine current drop related to those degrees. Any drop in current is caused by displacement current from the inductor to the outside world.

By the way, this is DIFFERENT than the self-resonance capacitance Cecil refers to. The capacitance causing a self-resonance is actually a

mixture of capacitance to the outside world (that DOES change
distribution) and capacitance from turn to turn (that does NOT change
slope of current except by how it affects effective inductance).

> 3. Then Tom, W8JI and his followers, with some "backing" from literature
> (plenty are wrong), some experiments, modeling, came to "prove" that it

> It appears to me that JI camp is coming from the theoretical end of it,
> applying laws of physics and theories that do not apply to the case in
> question.

First, it is not "my camp". I know people like to make things like this
personal issues, but they really are not. How things work are how
things work. I like to learn how things work just as much as anyone
else. The problem is when people start getting personal and saying
things they would never dare say to another person's face, I get
uncooperative.
Most people behave that way.

Putting personal issues aside, anything can be resolved.

> 5. Not so fast. JI camp vehemently defended their "equal current" case,
> using examples, modeling, tailored to support their claims, for some reason
> ignoring the reality, measurements, experiments done to set the coil in the
> spot where current can be, and is the same (no argument with that).

I can make current virtually equal at virtually any spot, and make it
very unequal at virtually any spot, just by changing the quality and
physical size of the loading inductor. I'll bet money on this,
provided we use real instruments.

The only time current will be substantially unequal will be when the
inductor has a large amount of capacitance to the outside world (acting
like a distributed network of displacement C's and series L's with
poor coupling) compared to the termination impedance at the inductor's
top.

I can take an antenna of specific height and vary current taper in the
inductor quite a bit just by changing the style of loading coil.

It is the idea that the loading coil drops a certain current because of
"electrical degrees" that is so untrue.

> 10. According W8JI camp, looking at the quarter wave loaded whip, the
> current goes up the radiator according to cosine curve, then is the same
> across the coil, then tapers to zero at the tip in the triangular shape
> (should be the rest of the cosine curve, but close enough approximation). We
> are talking about typical loaded resonant quarter wave ant, (not any coil in
> any circuit).

Again, this isn't my camp. Repeatedly trying to make this a personal
issue really just stops the scientific process.

The current distribution described above is indeed how an antenna works. This of course assumes the inductor is compact and has minimal distributed capaciatnce to the outside world compared to the termination impedance presented by the whip.

It can be proven.

The charge briefly piling up and then being sucked out of such an
inductor is the same place charge piles up and is sucked out of parts
of a transmission lines with standing waves on them. That is the
shunt capacitance to the rest of the universe from each part of the
coil or transmission line that momentarily stores this charge.

So, I guess the word you are trying to get me to say is "capacitance".
Nobody says it is "freakin' special", though. Its common as dirt.

What do I win?

> passing a point at one end of the coil is different than the
> coulombs/second passing the other end of the coil.

Sorry, you are wrong about that. Here's why. For simplicity,
let's assume the coil is lossless, 45 degrees long, and the
forward and reflected current magnitudes are both equal to
one amp. These assumptions are for purposes of illustration
only.

One amp of forward current is flowing into the coil and one
amp of forward current is flowing out of the coil. Charge is
balanced.

One amp of reflected current is flowing into the coil and one
amp of reflected current is flowing out of the coil. Charge is
balanced.

Note there is ZERO charge imbalance in the coil. The forward
and reflected currents are all there are and they are balanced.

The forward current at the bottom of the coil is 1 amp at zero
degrees. The reflected current at the bottom of the coil is 1
amp at zero degrees. Adding them together yields a standing
wave current of 2 amps at zero degrees. Do you know how to
do phasor math?

The forward current at the top of the coil is 1 amp at -45
degrees. The reflected current at the top of the coil is
1 amp at +45 degrees. Adding them together yields a standing
wave current of 1.414 amps at zero degrees. Do you know how
to do phasor math?

The standing wave current at the bottom of the coil is 2 amps.
The standing wave current at the top of the coil is 1.414 amps.
THERE IS *NO CURRENT IMBALANCE* BECAUSE THAT STANDING WAVE CURRENT
IS NOT REALLY FLOWING. IT IS JUST STANDING THERE. That's the
entire point.

> What happens to that imbalance in charge?

Imbalance in charge is a myth, an old wives' tale. There is NO
imbalance in charge. SEE ABOVE!

A 75m bugcatcher coil is NOT a small inductor. It is a slow-
wave structure with a velocity factor of about 0.017, both
measured and calculated. That gives my bugcatcher coil an
electrical length at 4 MHz of about ~60 degrees.

> This is because the inductor does not replace a certain "electrical
> degrees" and have a cosine current drop related to those degrees.

Sorry, Tom, Dr. Corum has proven you wrong on that score. A 1/2WL
thin-wire dipole has a perfect cosine curve. Other structures
deviate away from that perfect cosine curve. The coil certainly
deviates away from that perfect cosine curve. But if you look
at the current waveforms at:

http://www.k6mhe.com/n7ws/Loaded%20antennas.htm

figure 3, you can still see the outline of that cosine curve.

> I can take an antenna of specific height and vary current taper in the

You can take the same loading coil and move it around in a standing
wave environment and obtain any current distribution including current
flowing into both ends of the coil at once.

> It is the idea that the loading coil drops a certain current because of
> "electrical degrees" that is so untrue.

Sorry, Tom, that's just an old wives' tale of yours. Please respond

Seems you got sucked in by a myth, John. The forward current is equal
at both ends of the coil. The reflected current is equal at both ends
of the coil. That takes care of any question of charge imbalance. There
simply isn't any.

Assume the coil is 90 degrees long and that the forward current is one
amp and the reflected current is one amp.

At one end of the coil, the forward and reflected currents are 180
degrees out of phase. The standing wave current is zero.

At the other end of the coil, the forward and reflected currents
are in phase. The standing wave current is 2 amps.

Now do you see why standing wave current is considered not to be flowing?

Been there, done that, lived to tell the tale... Ended up putting the
wire spool in a metal can and feeding the entire can, so the wire on
the spool wasn't some weird inductor.

As other OPs point out, be aware of your local aviation authority
rules. In the U.S., flying things above a few hundred feet can garner
the wrong kind of attention.

In more rural areas, you may garner attention from people with rifles.

Discharge off the end of the wire tends to disagree with thin balloon
material; a few meter stringer of nonconductive line is a *good* idea
(or have a backup balloon and a backup supply of gas).

Helium is for pansies. Use hydrogen; it won't leak as fast (really --
those heliums are solitary little sneaky bastards and will get out of
anything, while hydrogens are diatomic and tend to stick around
longer).

Above all, have fun!

I don't disagree with anything you've said. The point I was trying to make was that the resemblance of a coil to a transmission line depends not only on the coil but also its capacitance to other objects -- and not to its relationship to traveling current waves. One thing I've seen done on this thread is to use the C across the inductor in transmission line formulas, appearing to give the coil a transmission line property all by itself and without any external C. This is incorrect.

>
>> Remove the shunt C and it ceases looking like a transmission line.
>
> How do I remove the shunt C of an inductor? With an active guarding
> scheme?

Actually, you can reduce it to a negligible value by a number of means. One I've done is to wind it as a physically small toroid. In the example discussed in the next paragraph, removing ground from the model reduces

the external C to a small enough value that the current at the coil ends become nearly equal. That of course isn't an option in a real mobile coil environment, but it illustrates that the current drop from one end to the other, which in some ways mimics a transmission line, is due to external C rather than reaction with traveling waves as Cecil claims. In my modification to Cecil's EZNEC file I showed how the coil behaves the same with no antenna at all, just a lumped load impedance. As long as the load impedance and external C stay the same, the coil behavior stays the same. This isn't, however, to discount the possibility of the coil interacting with the antenna's field. It just wasn't significant in that case.

>> The earlier example of the modification to Cecil's EZNEC model
>> illustrated this -- when the ground (the other side of the shunt
>> capacitor) was removed, the current drop across the coil disappeared.
>
> So whether or not this coil is acting as a slow wave transmission line
> in addition to being inductive depends on the surrounding fields and
> connections? I have no trouble with that.

Well, not a "slow wave" transmission line. We shouldn't confuse an ordinary lumped LC transmission line approximation with a true slow wave structure such as a helical waveguide (next item). The propagation velocity of the equivalent transmission line is omega/sqrt(LC), so the speed depends equally on the series L and the shunt C.

And let's talk for a minute about the coil "acting like" a transmission line. A transmission line is of course a distributed circuit. But you can make a single pi or tee section with lumped series L and shunt C which has all the characteristics of a transmission line at one frequency(*), including time delay, phase shift, characteristic impedance, impedance transformation, and everything else. If put into a black box, you wouldn't be able to tell the difference among the pi, tee, or transmission line -- at one frequency. You could even sample the voltage and current with a Bird wattmeter and conclude that there are traveling voltage and current waves in both cases, and calculate the values of the standing waves on either "transmission line". And this is with a pure inductance and capacitance, smaller than the tiniest components you can really make. With a single section, you can mimic any transmission line Z0 and any length from 0 to a half wavelength. (The limiting cases, however, require some components to be zero or infinite.) So you can say if you wish that the inductor in this network "acts like" a transmission line -- or you can equally correctly say that the capacitor does, because it's actually the combination which mimics a transmission line. But only over a narrow range of frequencies, beyond which it begins deviating more and more from true transmission line behavior. To mimic longer lines or mimic lines over a wider frequency range requires more sections.

So what can we conclude about inductors from this similar behavior? Certainly not that there's anything special about inductors interacting

with traveling waves or that inductors comprise some kind of "slow wave structure". The duality comes simply from the fundamental equations which describe the nature of transmission lines, inductances, and capacitances.

Because the LC section's properties are identical to a transmission line's at one frequency, we have our choice in analyzing the circuit. We can pretend it's a transmission line, or we can view it as a lumped LC network. If we go back to the fundamental equations of each circuit element, we'll find that the equations end up exactly the same in either case. And the results from analyzing using each method are identical -- if not, we've made an error.

The coil in the EZNEC model on Cecil's web page acts just like we'd expect an inductor to act. With ground present constituting a C, the circuit acts like an L network made of lumped L and C which behaves similarly to a transmission line. With ground, hence external C, absent, it acts like a lumped L. (There are actually some minor differences, due to imperfect coupling between turns and to coupling to the finite sized external circuit.) The combination of L and C "act like" a transmission line, just like any lumped L and C. And it doesn't care whether the load is a whip or just lumped components.

(*) It actually acts like a transmission line at many frequencies, but a different length and Z0 of line at each frequency. To mimic a single line over a wide frequency range requires additional sections.

>> As far as considering a coil itself as a "slow wave structure", Ramo

>
> I'll have to take your word for this limitation. But it seems to me
> that the length of the coil in relation to the wavelength and even the
> length of the conductor the coils is made of are important, also.

Important for what? No matter how long the coil or how many turns of the wire, a small (in terms of wavelength) inductor won't act like a slow wave structure or an axial mode helical antenna. This is for the same reason that a two inch diameter pipe won't perform as a waveguide at 80 meters -- there's not enough room inside to fit the field distribution required for that mode of signal propagation. There will of course be some point at which it'll no longer act as a lumped inductor but would have to be modeled as a transmission line. But this is when it becomes a significant fraction of a wavelength long. If the turns are very loosely coupled to each other, the wire length becomes more of a determining factor. As I mentioned in earlier postings, there's a continuum between

a straight wire and that same wire wound into an inductor. As the straight wire is wound more and more tightly, the behavior transitions from that of a wire to that of an inductance. There's no abrupt point where a sudden change occurs.

Dr. Corum gives a formula for calculating the velocity factor of coils
which meet a certain criteria. My 75m bugcatcher coil meets that
criteria. It's velocity factor calculates out to be 0.0175. It's
measured velocity factor is 0.015. That sounds like a "slow wave"
device to me.

FWIW, I was down at Quartzsite, AZ for the "Quartzfest" campout in
January and saw someone with a very nice helium balloon that looked
like it would be ideal for supporting antennas. It wasn't being flown
by one of the hams but by one of the off-roaders camped nearby so they
could find their way back to their campsite. I asked where they got
their balloon and they gave me this url:

http://www.arizonaballoon.com/generic3.html

The "ball" balloons look ideal for supporting a 1/4 /\ vertical for
160M.

There seems to be some confusion about just what a standing wave is.

A standing wave is the result of, and the sum of, two or more traveling waves. There aren't points which are "on" one or the other. If you can separately measure or calculate the values of the traveling current waves at any point, you can add them to get the total current (what Cecil calls "standing wave current") at that point. If you add the traveling current waves at each point along the line and plot the amplitude of the sum (that is, of the total current) versus position, you see a periodic relationship between the amplitude and position. It's this relationship which is called a "standing wave". It's so called because its position relative to the line stays fixed. It's simply a graph of the total current (the sum of the traveling waves) vs. position.

But the point is that the delay through the coil is somewhere
between 40 degrees and 60 degrees. When you tried to measure
the phase shift through a coil, you used standing wave current
phase to make the measurement. Standing wave current phase is
unchanging so you made a measurement blunder.

And there's no such thing as current imbalance based on standing
wave currents being different at each end of a loading coil.
"Current imbalance" is a concept that doesn't apply to standing
waves. "Phase rotation with position" is a concept that doesn't
apply to standing waves. Standing wave current is NOT ordinary
current. It is the superposition of two ordinary currents.

thanks.
my applications is this:
1.im designing an antenna switching array of four quarter wavelengths equally spaced apart in a circular manner @2.4 ISM band.
2.this is a doppler antenna system in which i switch(discrete lines from a microcontroller)) the antennas using rf pin diode(above 3GHz) around 30-50khz repetition rate .
3.from the discrete lines, i put a decoupling cap of 100nF to filter out high frequency generated by my micro(5th harmonics) and series it with an RF choke(choke the 2.4ghz signal coming from the antenna) direct to my switch(series) then a DC blck cap then the antenna. i have 4 arrays of these.also, i plan to have a DC feed after my antenna but could hardly find high-valued inductors with sfr about 2.4GHz hence i omitted it.

questions:
1.i doubt my isolation level for this setup.also,my reverse bias is only logic zero '0V'.would you recommend another setup with higher isolation at the same time cost-wise?
2.any recommendations on my possible pcb board layout with regards to ground/power planes?

thanks!

Now, cut that out! Standing waves have sinusoidal current swings that
vary in amplitude with location. Location includes the two ends of a
coil.

> The reflected current is equal at both ends
> of the coil.

Smile when you say that.

> That takes care of any question of charge imbalance. There
> simply isn't any.

Oh poo. At current nodes charge piles up and spreads out, on
alternating half cycles. For one half cycle, the pile is positive,
and for the next it is negative. This is a basic transmission line
concept. If transmission lines had no shunt capacitance, there would
be no place to put this charge. But there is, so it is no problem.
Whether the transmission line is coax, twin line or a slow wave helix
makes little difference. The process is similar. Isn't this what you
have been arguing?

> Assume the coil is 90 degrees long and that the forward current is one

Okay.

> Now do you see why standing wave current is considered not to be flowing?

I see how no current is considered to be flowing. Current is charge flowing. AC current is charge flowing back and forth.

But I see how two waves going in opposite directions create a standing wave where the magnitude of the sinusoidal current at different points along the standing wave have different magnitudes. And that between the nodes where the amplitude is zero, the phase of the current variation is constant.

Yeah, put it up, get on the air and enjoy...

You probably wouldn't notice the differences in antenna patterning or
gain, unless you have access to a really big test range and good
evaluation equipment.

You should, however, check the resonant frequencies after it's up, and
adjust the length (the extra tails, if needed can hang straight down if
needed without any reall effect on pattern). You've already got the
hard part done, getting the support ropes in place.

Agonizing over the minimal effect it has over a "perfect" antenna isn't
worth the time.

thanks

Yep. It is capacitance between each part of the coil and somewhere
other than the coil that makes it act like a transmission line.

Yes, smaller means less shunt capacitance. But less is not zero.
There is always some.

> In the example
> discussed in the next paragraph, removing ground from the model reduces
> the external C to a small enough value that the current at the coil ends
> become nearly equal.

Nearly equal, but not equal, yes. In some cases nearly is close
enough to equal that you can neglect it and get a reasonable
approximation. In other cases the approximation is not so reasonable.
It is a matter of degree.

I don't see it as a "rather", but as an effect that becomes non
negligible under some circumstances.

> In
> my modification to Cecil's EZNEC file I showed how the coil behaves the
> same with no antenna at all, just a lumped load impedance. As long as
> the load impedance and external C stay the same, the coil behavior stays
> the same.

Excellent. As long as there is external C, the coil acts in a non
lumped way, regardless of whether its current passes to an antenna or
a dummy load. This is the same result you would get with any
transmission line, also, except that the C is inside the line, instead
of all around it.

> This isn't, however, to discount the possibility of the coil

Per unit of length in the direction of propagation. Helical coils
have a lot of L in the direction of propagation, compared to straight
wire lines, don't they?

The question, I think is whether large, air core coils act like a
single inductance (with some stray capacitance) that has essentially
the same current throughout, or is a series of inductances with
distributed stray capacitance) that is capable of having different
current at different points, a la a transmission line. And the answer
must be that it depends on the conditions. At some frequencies, it is
indistinguishable from a lumped inductance, but at other frequencies,
it is clearly distinguishable. You have to be aware of the boundary case.

> Because the LC section's properties are identical to a transmission
> line's at one frequency, we have our choice in analyzing the circuit. We

> if not, we've made an error.

But a continuous coil is not a series of discrete lumped inductances
with discrete capacitances between them to ground, but a continuous
thing. In that regard, it bears a lot of similarity to a transmission
line. But it has flux coupling between nearby turns, so it also has
inductive properties different from a simple transmission line. Which
effect dominates depends on frequency.

> The coil in the EZNEC model on Cecil's web page acts just like we'd

> is a whip or just lumped components.

I agree with the last sentence. The ones before that seem self
contradictory. First you say it acts just like an inductor, then you
say it acts like a transmission line. These things (in the ideal
case) act very differently.

> (*) It actually acts like a transmission line at many frequencies, but a
> different length and Z0 of line at each frequency. To mimic a single
> line over a wide frequency range requires additional sections.

I think I agree with this. Either a simple transmission line or a
simple inductance description is incomplete. It does some of both.

But its propagation speed will be slower than it would be if the wire
were straight. don't know if that qualifies it for a "slow wave" line
or not.

Why can't it be modeled as a transmission line before it is that long?
will you get an incorrect result, or is it just a convenience to
model it as a lumped inductor, instead?

Sure there are. If there is a standing wave on a wire, and you have a tiny current transformer sensor you can slide along the wire, you can measure the instantaneous current (or the RMS) at any point along the wire. If the sensor sits at a single point and sees an AC current, you have no way, from this one measurement, if this current is the result of a standing wave (two oppositely traveling equal waves adding), or a single traveling wave, or any combination of traveling waves of different amplitudes. You know only the net current at that point.

> If you can
> separately measure or calculate the values of the traveling current

I have no disagreement with this description.

> current. It is the superposition of two ordinary currents.

You two are so close to agreement. Standing waves have a current that varies with position. The fact that the EZNEC simulation of a loading coil shows differing current in a situation that is a fairly pure standing wave situation (more energy bouncing up and down the antenna than is radiating from it) means that the RMS current will vary along the standing wave. And, since the simulation shows a different current magnitude at the two ends of the coil, a significant part of a standing wave cycle must reside inside the coil (more than the physical length between the two ends of the coil would account for).

In one case (the highest frequency one) the phase of the current even reverses from one end of the coil to the other, as well as an amplitude variation, indicating that a standing wave node occurs some where inside the coil, and the two ends are on opposite ends of that node. If the two currents had been equal, but 180 degrees out of phase, the node would have been in the center of the coil.

Cecil wrote,
"The forward current is equal at both ends of the coil. The reflected current is equal at both ends of the coil."

If that's really true, then the net current is precisely equal at both ends of the coil. I thought you had been claiming that the current is different at each end. Which way is it going to be? If they are different phases, then they are NOT equal. If they are different phases, where does the phase shift COME FROM? If I allow a wave in one direction ONLY and the currents at the two ends are DIFFERENT in phase, WHAT HAPPENS inside the coil to make them different? Where does the extra charge come from, or go to?

It's all very simple. Yawn.

Hint: Replace the coil with a piece of coaxial transmission line, formed into a loop so the input and output ends are adjacent. Short the outer conductors together and notice that nothing changes in terms of the voltages across each end of the line and currents in the center conductors at each end. Note the difference in current at the two ends of the line, and note the current in the single outer conductor terminal of this three-terminal system. Notice that the sum of all three currents at every instant in time is essentially zero (current direction taken as positive going into each terminal). Got it yet? Do you understand WHAT it is, besides the inductance, that allows a coil to look like a transmission line? Do you understand that the mode is not quite TEM, so some of the usual TEM transmission line behaviour is not going to hold?

Cheers,
Tom

Cecil wrote, among other things,
"One amp of forward current is flowing into the coil and one
amp of forward current is flowing out of the coil. Charge is
balanced."

Absolutely NOT! You said the phase difference between the two ends is 45 degrees. Therefore, charge "input" and "output" is balanced ONLY twice during a cycle, when the instantaneous currents are the same. No phase need apply here: we're talking INSTANTANEOUS currents. The rest of the time, there's net charge accumulating inside the coil half the time, and net charge coming out the other half the time. GOT IT yet??? You do NOT need phasor math to do this!

WHAT does that charge represent, Cecil? C'mon, you can say it...

Cheers,
Tom

So, why is it that you need "tens of microhenries"?? Having built (after doing some redesign on it) a doppler-scanning antenna before, I'm having a hard time seeing why you would need that sort of inductance in your antenna switch. I guess you better use some low capacitance PIN diodes, and resonate them with inductances to reflect a high impedance back to the "off" antennas...and I can see a need for RF chokes that represent a couple hundred ohms reactance at 2.4GHz, but that's only a few nanohenries, not tens of microhenries.

You should be able to have one diode forward biased and the rest reverse biased by the remainder of your logic voltage level...if you want more (why?), use high voltage open collector gates as drivers, or just four discrete transistors.

Layout: make it very symmetrical, so each antenna behaves the same way. Standard microstrip techniques should work fine. If you're not used to working with this stuff, I highly recommend enlisting help from someone with experience, at least to give you occasional guidance. In-person help will be much more useful than what you get on r.r.a.a.

Cheers,
Tom

No, the coil is acting in a lumped way whether the C is there or not. A combination of lumped L and lumped C mimics a transmission line over a limited range. But neither the L nor C is acting as more or less than a lumped component. All the "transmission line" properties I listed in my last posting for the LC circuit can readily be calculated by considering L and C to be purely lumped components.

>> Well, not a "slow wave" transmission line.
>
> Its propagation is a lot slower than a normal transmission line based on
> straight conductors, isn't it?

There's more L per unit length than on an equal length line made with straight wire, so yes the propagation speed is slower. But there's nothing magic about that. A lumped LC circuit can be found to have exactly the same delay and other characteristics of a transmission line, and it can do it in zero length.

>
>> We shouldn't confuse an ordinary lumped LC transmission line

> Heaven forfend. ;-) I am not clear on the difference.

A slow wave structure is a type of waveguide in which the fields inside propagate relatively slowly. Ramo and Whinnery is a good reference, and I'm sure I can find others if you're interested.

Yes indeed, as discussed above. And as I said above, you can get plenty
of delay from a lumped L and C of arbitrarily small physical size.

Yes. It's a continuum, going from one extreme to the other. As Ian has
pointed out several times, any theory should be able to transition from
one to the other. The example Cecil posted on his web page was one for
which the L could be modeled completely adequately as a lumped L, at
least so far as its current input and output properties were concerned.
Being a significant fraction of the antenna's total length, it of course
does a substantial amount of radiating which a lumped model does not.

Yes, that's correct. But if it's short in terms of wavelength, a more
elaborate model than a single lumped inductance won't provide any
different results.

>

> act very differently.

Let me try again. The combination of L and the C to ground act like a
transmission line, just like a lumped LC acts like a transmission line.
With the ground removed, there's nearly no C, so there's very little
transmission-line like qualities. Of course you could correctly argue
that there's still a tiny amount of C to somewhere and so you could
still model the circuit as a transmission line. The equivalent
transmission line would have very high impedance and a velocity factor
very near one. Such a transmission line is difficult to distinguish from
a plain inductor.

> or not.

That's the third time for this. Sure. A theoretical lumped inductor and
a theoretical lumped shunt capacitor can have a very slow propagation
velocity, and with no physical length at all. I'm failing to see why
this has some special relevance.

>> This is for the same reason that a two inch diameter pipe won't

Hm, I tried to explain that, but obviously failed. You can model it
either way. If you've done your math right, you'll get exactly the same
answer, because you'll find that you're actually solving the same equations.

No, you're misinterpreting what you're seeing. Imagine an LC L network with theoretically lumped series L and shunt C. If you look at the currents at the input and output of the perfect inductor, you'll find that they're exactly the same. If, however, you look at the currents in and out of the *network* you'll see that they're different, because of current going to ground through the C. And, as I said before, you can even pretend it's a transmission line and measure forward and reverse traveling waves and a standing wave ratio. But with zero length, there can be no standing waves inside the inductor. Yet the terminal characteristics of the network are the same as a transmission line. You don't need to imagine standing waves residing inside the inductor in the LC circuit, and you don't need to imagine them inside the inductor in Cecil's model, either.

When you look at the currents reported by EZNEC for the model on Cecil's web page, the current at the top of the coil is the equivalent to the *network* current described above. It's the current flowing through the inductance minus the current being shunted to ground via the C between the coil and ground. You can tell just how much this is by looking at my modified model and subtracting the current going into the coil from ground from the current going into ground from the added wire. They're not the same -- the difference is the displacement current through the C from the inductor to ground. When I removed the ground, you could then see the current flowing through the inductor, by itself, without the current being shunted off. And lo and behold, it's nearly the same at both ends of the inductor, showing that the inductor is behaving very much like a lumped L. Only in conjunction with the C to ground does the combination mimic a transmission line -- just like any other lumped LC circuit.

Of course, at some length and/or poorness of interturn coupling, a coil will start behaving in a way we can't adequately model as a lumped L. But that's not the case here.

>point?

Electronic components are exactly that stupid. They have no conception of traveling or standing waves. They react simply to the voltages and currents they experience at their terminals.

As far as current is concerned, that means the simple movement of charge past a single point.

You see a larger picture of the whole antenna, so you can choose many different ways to theorize about it. But your theory cannot be correct if it requires that components behave in different, special ways according to the way you happen to be thinking about it at the time.

So many words trying to avoid the real issue which is: What is
the percentage of a wavelength occupied by a loading coil. It
doesn't matter what the size of the coil is. In the real world,
a loading coil occupies a certain percentage of a wavelength.

For a small coil, that percentage will be small. For a large
coil that percentage will be large.

We have had to throw out your phase measurements using the phase
of standing wave currents because that phase you used is unchanging
whether in a wire or in a coil. Your phase measurements tell us
zero information about the delay through a coil.

That leaves us only with indirect measurements based on the self-
resonant frequency of the coil in the mobile environment or the
phase information left in the standing wave current amplitude over
the 90 degree antenna.

My self-resonant frequency measurements indicate that a 75m loading-
coil occupies 40-60 degrees of a 360 degree wavelength. That's
11%-17% of a wavelength. Dr. Corum's papers agree with that
estimate.

Another way of estimating the percentage of the antenna occupied
by the loading coil would be to plot the current segments from
feedpoint to tip. Then draw a cosine wave on the same graph with
0 degrees at the feedpoint and 90 degrees at the tip. A rough
estimate of the percentage occupied by the coil would be the
slice of the cosine wave from the bottom of the coil to the
top of the coil.

Mere words are not going to change the percentage of a wavelength
occupied by a real-world loading coil.

> been arguing?

If the forward traveling wave is equal in magnitude at both ends of the
coil, there is no net storage of energy due to the forward traveling wave.

If the reflected traveling wave is equal in magnitude at both ends of the
coil, there is no net storage of energy due to the reflected traveling
wave.

Superposing those two waves still results in no net storage of energy.
Sorry, got to hit the road.

Dr. Corum says the boundary is 15 degrees, or 0.04 wavelength.
Another place in his class notes he says that if 1/6 of a wavelength
of wire is used to make the coil, the lumped-circuit model will NOT
work. My 75m bugcatcher coil is more than 1/6 of a wavelength of
wire.

> But a continuous coil is not a series of discrete lumped inductances

> effect dominates depends on frequency.

Dr. Corum has a test equation to see if his velocity factor equation
applies. The test is: 5*N*D^2/lamda(0) <= 1 where N is number of turns,
D is the diameter of the coil, and lamda(0) is the self-resonant
frequency. If this equation is satisfied, then equation (32) applies
for velocity factor. For my 75m bugcatcher coil, the test number is
0.4 <= 1 and the velocity factor equation yields 0.0175. That's certainly
a slow wave device.

> But its propagation speed will be slower than it would be if the wire
> were straight. don't know if that qualifies it for a "slow wave" line

A velocity factor of 0.0175 for a 75m bugcatcher seems to qualify.

But if one it smart enough to slide the sensor up and down the wire
and note the phase is fixed and unchanging, one knows he is dealing
with a standing wave.

>> If you add the traveling current waves at each point along the line
>> and plot the amplitude of the sum (that is, of the total current)

And that's all it is - the sum of two traveling waves. A standing wave
has no separate existence of its own. It is an artifact of superposition.

And since a significant part of a standing wave cycle resides inside
the coil, it occupies a non-negligible percentage of a wavelength.
By every valid method, measured or calculated, a 75m bugcatcher
coil occupies tens of degrees of a wavelength (out of 360 degrees).
My best estimate is 60 degrees in a 75m mobile antenna.

Yes, if a current node exists inside a coil, the standing wave currents
are flowing into the coil at the same time from both ends and 1/2 cycle
later they are both flowing out of the coil at the same time. Wonder
how a lumped-circuit inductance handles that? :-)

I was speaking above about the magnitudes only, not the phases.
It was clear from the rest of my posting that was the assumption.
The fact that you attempted to change the meaning by trimming is
noted.

So to be perfectly clear, here is my statement re-worded using
a 45 degree phase shift through the coil.

The forward current magnitude is equal at both ends of the coil.
The reflected current magnitude is equal at both ends of the coil.

At the bottom of the coil, the forward current is 1 amp at zero deg.
At the bottom of the coil, the reflected current is 1 amp at zero deg.
At the bottom of the coil, the standing wave current is 2 amps at
zero deg.

At the top of the coil, the forward current is 1 amp at -45 deg.
At the top of the coil, the reflected current is 1 amp at +45 deg.
At the bottom of the coil, the standing wave current is 1.4 amp at
zero deg.

I asked if you knew how to do phasor math but you trimmed out that
phasor math part of my posting.

Give us a break, Tom. Of course, we are *NOT* and never have been talking instantaneous currents. All currents ever discussed concerning this subject have been RMS currents. That's just your instantaneous strawman. Long term charge accumulation is averaged over many cycles. There is simply none of that because the traveling waves are not storing any net charge inside the coil. How can you get so desperate as to play such silly games?

My statement obviously meant: One amp of RMS forward current is flowing into the coil and one amp of RMS forward current is flowing out of the coil. Average charge is balanced.

Even though the standing wave current is different at each end of the coil, the average charge into and out of the coil is still balanced.

That is a presupposition of the lumped-circuit model. You cannot
use that to try to prove the validity of the lumped-circuit model.

My 75m bugcatcher coil has a velocity factor of 0.0175 calculated,
0.015 measured. That's a slow wave structure.

> Yes indeed, as discussed above. And as I said above, you can get plenty
> of delay from a lumped L and C of arbitrarily small physical size.

Just as you can from an arbitrarily large 75m bugcatcher coil.
No extra capacitance needed.

> With the ground removed, there's nearly no C, so there's very little
> transmission-line like qualities.

You forgot to tell us how to remove the ground from my 75m bugcatcher
antenna system mounted on my GMC pickup.

> That's the third time for this. Sure. A theoretical lumped inductor and

> this has some special relevance.

Because you reported zero phase shift through a real-world loading coil.
Since standing wave current phase is unchanging, you blundered badly.

The real question remains: What percentage of a wavelength does a 75m
bugcatcher coil occupy in a 75m mobile antenna installation? The answer
is tens of degrees.

The main effect in a standing wave environment are the forward
and reflected phasors rotating in opposite directions. The
standing wave current is ZERO when those phasors are 180 degrees
out of phase. The standing wave current is maximum when those
phasors are in phase. "Current going to ground through the C"
is not even required.

> But with zero length, there
> can be no standing waves inside the inductor.

You keep saying stuff like this as if a zero length inductor
actually existed in reality. Wake up, Roy, and smell the
roses. That zero length inductor exists only in human minds.

> When you look at the currents reported by EZNEC for the model on Cecil's

Huh? How do you explain the current at the top being greater than
the current at the bottom of the coil? Is the coil sucking current
from the ground?

I don't have AO Dave, so a description will work.

That sounds like the problem I am seeing. With a 3-5 WL long V, I have
about the same gain as a three element Yagi. But I'll still try to
model your antenna with 5wl legs and 44 degree angle. Thanks.

That's utter nonsense Cecil, and why people aren't buying into your misconceived theories.
Maybe you can take some time to rethink your position while on vacation.

A two-terminal network that transforms impedance, now there's a concept!

An inductor behaves exactly the same way in or out of your so-called standing wave environment. It follows the same rules all the time.

Since your theory says otherwise, it has to be wrong.

Wave theory is just another way of analyzing a complex system. It doesn't change how things inside the system behave.

Let's focus on one thing at a time.

You claim a bug cather coil has "an electrical length at 4MHz of ~60 degrees". That concept is easily proven false, just like the claim a short loaded antenna is "90-degree resonant". Both can be shown to be nonsense pictures of what is happening.

Assume I have a 30 degree long antenna. If the loading inductor is 60 electrical degrees long, I could move it anyplace in that antenna and have a 90 degree long antenna.

We all know that won't happen, so what is it you are really trying to say?

Precisely and specifically NOT that!

Let me have one last try:
The human observer sees a larger picture of the whole antenna, and can choose many different ways to theorize about it. But a theory cannot be correct if it requires that components behave in different, special ways according to the way a person happens to be thinking about it at the time.

If you cannot see that statement as a fundamental principle of scientific logic, then I have run out of ways to tell you.

Replacing the part of my previous message that you snipped:

>>Electronic components... have no conception of traveling or standing waves. They react simply to the voltages and currents they experience at their terminals.<<

They cannot behave in different ways for different types of current. If you want to analyse the current into different parts and give them different labels, a pure, lumped loading inductance MUST still respond to every kind of current in the same way.

>It is not my theory. It is the distributed network
>model which you apparently reject.

No, I reject your incorrect applications. The reasons may look simple but they are absolutely fundamental.

Sorry, Tom, that's distributed network analysis, something you
and others seem to be totally ignorant of and confused by.

I get emails every week from people who are buying into the
distributed network analysis. Otherwise, they are forced to
accept your magical thinking about reality.

> A two-terminal network that transforms impedance, now there's a
> concept!

It isn't a two-terminal network. It is a single-wire transmission
line over ground. It has forward and reflected waves working against
ground, similar to a two-wire transmission line.

> An inductor behaves exactly the same way in or out of your so-called
> standing wave environment. It follows the same rules all the time.

Quoting Dr. Corum again: "There are no standing waves [allowed]
on a lumped element circuit component. (In fact, lumped-element
circuit theory inherently employs the cosmological presupposition
that the speed of light is infinite, as every EE sophmore should
know.)"

"Lumped circuit theory fails because it's a theory whose
presuppositions are inadequate. Every EE in the world was warned
of this in their first sophmore circuits course."

Tom, where did you attend your sophmore EE classes?

> Since your theory says otherwise, it has to be wrong.

It is the distributed network theory, Tom, developed to handle
just such cases of failure of the lumped-element model. Both
models work in some instances. The distributed network model
works when the lumped-element model fails.

> Wave theory is just another way of analyzing a complex system. It
> doesn't change how things inside the system behave.

Exactly! But lumped-circuit theory changes how things inside
the system behave when standing waves are present. One can
observe its magical effects in your explanations. Unfortunately,
it is not supposed to change anything. When a model tries to change
the laws of physics, it's time to move to a more power model that

doesn't.

Bottom line: By every valid measurement and calculation, a 75m
bugcatcher coil occupies roughly 60% of a mobile antenna.

Hi Tom et al,

This is from the AO library:
F=24.94

The vertex is at the origin: 0,0
X,Y of 1st leg is 185.44', -74.92' #12 wire
X,Y of 2nd leg is 185.44', 74.92' #12 wire

Fed at the origin and modeled in free space

AO reports
Z= 255- J706
Forward gain= 11.34dBi
F/B 2.70dB

Hope this is useful,

Dale W4OP

Well, I've been challenging you to do just that for weeks now and
so far, nothing. Please note the contradiction between your statement
above which says an antenna doesn't have to be 90 degrees long to be
resonant and your statement below which says it does. Would you please
make up your mind?

> Assume I have a 30 degree long antenna. If the loading inductor is 60
> electrical degrees long, I could move it anyplace in that antenna and
> have a 90 degree long antenna.

This again demonstrates your misconceptions. Please pay attention
this time.

When my 75m bugcatcher coil is configured as a base-loaded coil
with a 7 foot whip, it occupies ~60 degrees of antenna. The 7
foot whip occupies ~10 degrees of the antenna. The total length
is only ~70 degrees, not 90 degrees. That 90 degrees is just your
strawman and you even contradicted yourself above.

The antenna doesn't have to be 90 degrees long. What has to
happen is for (Vfor+Vref)/(Ifor+Iref) to be resistive at the
feedpoint. There are many possibilities for that in antennas
not 90 degrees long. I gave one such example possibility
weeks ago. Perhaps you missed it.

I haven't measured the number of degrees occupied by a center-
loaded 75m bugcatcher coil. Since the inductance of the
center-loaded coil must be increased when moved from the base
to the center, it would occupy more of the antenna at the center
than it does at the base for the same resonant frequency.

The 70uH 75m bugcatcher coil occupies ~60 degrees when installed
at the base.

For the same resonant frequency and same length for the rest of
the antenna, a center-loaded coil would need about double that
reactance, making it about 1.4 times the size of the base-loaded
coil. So I would estimate that the center-loaded coil is occupying
~80 degrees of the antenna, much closer to a total of 90 degrees
than the base-loaded version.

Cecil,

Well, I guess it's back to the math books for me. I mistakenly thought that currents described by cos(kz-wt) and cos(kz).cos(wt) would be considered "instantaneous" currents. If they're really RMS, well . . .

I am curious about one thing, however. It would seem that all of this "averaging", "RMS", and "net" is a bit inconsistent with digging into a distributed network problem, which you insist is the only valid description. Everything can vary in time and space in a distributed network. Certainly these consolidating functions are useful for a general overview, but how can you learn anything about the details of a complex system by averaging and netting?

73,
Gene

It means the lumped-circuit model works where the distributed-
network model fails. That is false. It is just the opposite.
the distributed-network model works where the lumped-circuit
model fails.

> The difference is that my views join up with the rest of human knowledge
> about antennas and circuit behaviour.

Only up to where the coils are 15 degrees long. Then the distributed
network model must be engaged to avoid blunders exactly like you
and others are making.

> Yours don't. They fail that crucial test.

Distributed network analysis fails the test??? Please provide
an example. The IEEE would probably publish a paper on such.

Cecil, quit trying to pedal that bullshit. The currents at the two ends of the coil are NOT the same if they are different phases. It is the phase difference that lets you establish different standing wave currents at the two ends, when there's a travelling wave in each direction. So if the phase is different, then clearly there is net current going into the coil half the cycle, and net current coming out of the coil half the cycle.

Go ahead and do it with your travelling wave and phasors. It will work just as well as instantaneous currents. You will find a net current into the coil at some phase. Clearly the phasor notation is just a simplification of instantaneous currents for the case of sinusoidal excitation, and the answers darned well better be the same, or you better throw out your phasor notation.

OF COURSE the AVERAGE charge in and out is balanced! If it weren't, then you have a DC current with nowhere to go. This is a linear system we're modelling here, with no way to convert a sinewave to DC.

So tell us what net AC current into a component represents, and we'll just about be there.

No, Cecil, I did not try to change the meaning by trimming. I was simply pointing out a basic flaw in your whole development. You use the differing phase to establish that a travelling wave in each direction results in a difference in the standing wave current at each end, but then you try to use amplitude only to show no net current into the coil. Now use the SAME phase difference you used to develop the standing wave, and use it to determine the net AC current into the coil, AT SOME PHASE. Now use the same phase difference in the other direction to see that it also results in a net AC current AT SOME PHASE. AND for the case where there is a standing-wave current difference between the two ends of the coil, the net coil current is EXACTLY as predicted by the vector sum of the two travelling wave net currents.

Now you decide. Can I do phasor math? Do you need a specific example with numbers, or can YOU work that out yourself? Suggest you use the example from your previous posting. If that causes any difficulty, try it with 180 degrees phase shift through the component. I've done it, and it keeps giving me precisely the same answer as a full cycle of instantaneous currents.

Tom,

Some questions.

What is "good" gain?

What frequency?

How high?

Try this at 10 MHz. Dimensions in feet.

End 1 End 2

X Y Z X Y Z

W1 0.0 0.0 100.0 245.0 -114.2 100.0
W2 0.0 0.0 100.0 245.0 114.2 100.0

OK lets get me some educating here.
I understand that, say quarter wave resonant vertical (say 33 ft at 40m) has 90 electrical degrees.
Is that right or wrong?

The current distrubution on said (full size) vertical is one quarter of the wave of 360 deg. which would make it 90 degrees. Max current is at the base and then diminishes towards the tip in the cosine function down to zero. Voltage distribution is just opposite, min at the base, feed point and max at the tip. EZNEC modeling shows that to be the case too.
Is that right or wrong?

If we stick them end to end and turn horizontal, we get dipole, which then would be 180 deg. "long" or "180 degrees resonant".
If not, what is the right way?

If I insert the coil, say about 2/3 up (at 5 ft. from the bottom) the shortened vertical, I make the coil size, (inductance, phys. dimensions) such that my vertical will shrink in size to 8 ft tall and will resonate at 7.87 MHz.
I learned from the good antenna books that this is still 90 electrical "resonant" degrees.
Maximum of current is at the feed point, minimum or zero at the tip.

If you stick those verticals (resonant) end to end and horizontal, you get shortened dipole, with current distribution equal to 180 degrees or half wave. Max current at the feed point, minima or zero at the tips. (RESONANT radiator)

How many electrical degrees would that make? How do you arrive at that?
Why is this a nonsense?

Can we describe "pieces" or segments of the radiator as having proportional amount of degrees corresponding to their physical length, when excited with particular frequency?

If I can be enlightened about this, we can go then to the next step.

Answers, corrections please.

With reverse bias, the PIN diode looks like a capacitance. Resonate
that capacitance with a parallel inductor, and you'll do more for
isolation than you will by increasing the reverse bias from 5V to 40V.
I assume you're not dealing with signals that are several volts in
amplitude...

(My opinion follows, please correct me. Dang, I should put that in my sig.)

In reality, there is no such thing as a two terminal network, unless one of those terminals is grounded. For all other cases, there is an unavoidable implied ground terminal that covers all the stray capacitance of the device.

So the bug catcher coil is recognized as a 3 terminal device, with ground being the third terminal. It can be modeled as a pi, T or transmission line structure, as long as you want to understand what to quantify it at only one frequency (or a narrow band), and the choice is arbitrary. If you are concerned with modeling a large frequency range (that goes well past the first self resonance), one of those models (or a more complicated one) will be superior.

>> "The current in a typical loading coil in the shortened antennas
>BIGSNIP of a howler
>

Hi David,

I would have thought so on its completion. However, the problem of
the poor specification has given rise to the prospects that Yuri's
vertical was never resonated by the loading coil at all. I find it
strange that I had to wade through a ton of verbal chatter to glean
minutiae such as:

"(with hat) and reresonating"

where the coil had been moved throughout the length of the radiator
and the system "reresonated" back in the shack. The long and short of
this was I struggled to make the antenna resonant in the 40M band, and
achieved it with yet another shortfall of specification. The coil
itself was barely mentioned except for its diameter.

Sure, a picture was provided, but those meters that I used to scale it
look very much like 3ï¿½" panel mounts and are as wide as the coil. By
using them as a benchmark, I reckoned the coil for being 20" long at 4
turns per inch. Later, when I accepted the "reported" coil diameter
of 2ï¿½", I forgot to shorten the coil to 10" and increase the pitch to
6tpi. Needless to say results need to be revisited, but the only
change will be on the wrong side of the decimal point for those
"debating" the matter.

When thread lengths get to be 500+ the participation has long ceased
to be about any technical content.

Like those who argue that POS EZNEC reports erroneous results when
they use it wrong; this is basically the story of the man who went to
the doctor to complain:
"It hurts when I do this!"
Doctor:
"Stop doing that."

Hi Yuri,

At your page you assert:
> "The current in a typical loading coil in the shortened antennas
> drops across the coil roughly corresponding to the segment of the
> radiator it replaces. "
so I must presume this is part and parcel to your question above and
the coil is part of that proportionality where all segments combine to
90ï¿½.

On the other hand, Cecil is only willing to allow:
On Wed, 22 Mar 2006 23:48:11 GMT, Cecil Moore <mycall@hotmail.com>
wrote:
>+/- 50% accuracy.

Now, given that you might describe a radiator whose vertical sections
add to 30ï¿½, then it follows from your page's assertion that the coil
must represent 60ï¿½. Cecil, again, would give pause and restrict that
to some value between 30ï¿½ and (oddly enough) 90ï¿½. The total structure
then represents a 60ï¿½ to 120ï¿½ electrically high verticle.

The long and short of this (a pun) is that Cecil has argued you into a
rhetorical corner where it is highly unlikely that the whole shebang
is ever 90ï¿½ long - by parts that is. Or as a Hail Mary argument, you
could simply assert that the range encompasses the right value for
your assertion above, but then anyone could use the same logic to say
all loaded antennas are only 70ï¿½ electrically tall and another could
boast 110ï¿½ and you couldn't dispute them. (Yes, you could, of
course, this is a newsgroup afterall.)

Perhaps you would like to argue this for yourself (I don't pay much
attention to Cecil anyway as this +/- 50% slop factor accounts for).

And a transmission line mimics a lumped LC network, over a limited range.

We are still talking about an antenna loading coil, aren't we? This is a coil made with a length of conductor that is a significant fraction of a wavelength at the frequency of interest, and with low coupling between the most separated turns. And with non zero capacitance of every inch of that length to the rest of the universe and to neighboring inches of the coil. To say it is acting in a lumped way I can only assume that you mean a lumped model of it can be produced that predicts its behavior with an acceptable approximation at a given frequency. Sure, at a single frequency, lots of different models can be useful. I am trying to get inside the black box and understand how the device acts as it acts, not discover what simplified models might approximate it under specific conditions.

Then we agree on this. Perhaps the words "slow wave transmission
line" have been copyrighted to mean a specific mechanism of slow wave
propagation, not all mechanisms that propagate significantly slower
than straight wire transmission lines do. If so, I missed that.

...

You keep going back to how lumped components can mimic actual
distributed ones (over a narrow frequency range). I get it. I have
no argument with it. But why do you keep bringing it up? We are
talking about a case that is at least a border line distributed device
case. I am not interested in how it can be modeled approximately by
lumped, ideal components. I am interested in understanding what is
actually going on inside the distributed device.

A lumped inductor has no stray capacitance. Those also have to be
added to the model, before the effect would mimic the real coil
(neglecting radiation).

But in the real world, the capacitance is always there. It varies,
depending on the location of the coil, but it never approaches zero.

3417. Current across the antenna loading coil - from scratch

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-23 17:50:32 UTC
From: Yuri Blanarovich <K3BU@optonline.net>
Message-ID: <UdBUf.15$t06.3@fe12.lga>
Source record: 62378

OK, I have been accused of being wrong, claiming that current across the antenna loading coil is or can be different at its ends.
I and "my camp" say that we are seeing somewhere 40 to 60 % less current at the top of the coil, than at the bottom, in other words, significant or noticeable drop.
W8JI and "his camp" are claiming it can't be so, current through the coil has to be the same or almost the same, with no significant drop across the loading coil.

Let's start the fresh thread and trace step by step where I went wrong.

Just reminder that we are talking typical situations, as for example real 40 m (or 80 m) mobile whip with loading coil about 2/3 up the radiator. We are talking about resonant electrical quarter wave monopole. We are talking about standing wave RF current that can be measured with RF ammeter and is shown and plotted in modeling programs like EZNEC.

Here we go:

<w8ji@akorn.net> wrote in message >
> Let's focus on one thing at a time.

Got it. Same for any pi, T, or more complicated LC network.

> And, as I said before, you can
> even pretend it's a transmission line and measure forward and reverse
> traveling waves and a standing wave ratio.

Yes. Under some specific conditions.

> But with zero length, there
> can be no standing waves inside the inductor.

Yes. There are no waves in a single ideal lumped component, so there
can be no waves inside any of them, only a phase shift between the
voltage across them and the current through them. But a network made
of them can mimic lots of processes that internally involve
propagation of waves, including the phase shift between voltages
across the terminals and current into the terminals, and even group
delay, but only over narrow frequency range. It is a model with this
severe limitation.

> Yet the terminal
> characteristics of the network are the same as a transmission line. You
> don't need to imagine standing waves residing inside the inductor in the
> LC circuit, and you don't need to imagine them inside the inductor in
> Cecil's model, either.
(snip)

Whether or not we need to imagine them to picture what is happening at
the terminals is not the question at hand. The question in my mind is

what is the actual mechanism, inside the device in question that is causing the effects we see at the terminals. I am not interested in the full range of models that predict the effect, but in the actual cause. I accept that my motivation is not necessarily the same as yours.

Over a complete cycle, I agree, Within a single cycle, standing waves
slosh charge back and forth between adjacent current nodes, piling up
positive charge at one and negative charge at the next. This is the
reason that the voltage peaks at the tip of a quarter wave antenna.
It is a current node (because current has no place to go from there),
so charge piles up and produces voltage. But over a complete cycle,
the net charge movement is zero (the positive piles are he same size
as the negative piles).

Same thing I said last paragraph.

> Superposing those two waves still results in no net storage of energy.

Richard and everybody,

Let's try again from scratch, fresh, I will try to go step by step, so there are no ambiguities, twists and turns to each own's la-la land.

Cecil is on well deserved break, so I am am on my own, stuck on whatever it might be.

I will not continue, unless there is an agreement at each point, I go sloooow, for the benefit of mine and others who duntgetit.
The "camp" think is to signify two groups claiming the different behavior of the current in the antenna loading coil. No intent to punish anyone.

Please go to the new thread that I started.
"Current across the antenna loading coil - from scratch"
If needed I will post pictures on my web site, unless there is a way to do it here.

Thank you!

Yuri, K3BU.us

I guess this depends on the official definition if "slow wave". It
may already be taken for something specific and limited. It may be
something like high frequency has come to mean an arbitrary frequency
band. This group is the first place I have come across the term.

Another point, entirely. My point is that current has a point
definition, and standing wave current is certainly indistinguishable
from traveling wave current, at a point. Current is current.

Patterns of current over length is another subject. But you keep
saying that there is something different about current in a standing
wave. There isn't. It is the pattern of current distribution over
time and distance along a conductor that is different with a standing
wave.

It is a nit, but it is snagging other people in the discussion, too,
so I thought it would help to clear it up.

> how a lumped-circuit inductance handles that? :-)

Of course, it can't. But a lumped LC network made of perfect, ideal components can be constructed that mimic the terminal conditions of the coil in question to any degree of accuracy desired. The caveat is that you may not explore much of a frequency range if you expect this idealized model to remain a good mimic. At another frequency, you have to rebuild it to copy the effects at that frequency. The broader the frequency range of such a model, the more complexity it must have.

A model that works over a wide range of frequency (including through multiples of the self resonant frequency) would be simplest if it modeled the propagation effects inside the coil, explicitly (with a distributed concept), rather than as an effect of a large network of ideal Ls and Cs.

I am beginning to think that, for many, this is a discussion, not about actual causes of effects, but of preferred models.

And preference can be very personal.

I apologize if I am getting too philosophical, but I just began re-reading "Zen and the Art of Motorcycle Maintenance", and it may be having this effect on me. But then, getting involved in this discussion may be what made me think of that book.

Hi Yuri,

Are you then abandoning your web page?

You know, it would seem to be better effort to stick with the
demonstrables there and to make sense of them, than to wander the
intellectual landscape of "theory."

>OK lets get me some educating here.
>I understand that, say quarter wave resonant vertical (say 33 ft at 40m) has
>90 electrical degrees.
>Is that right or wrong?

If you cannot define your limits of error, then Cecil is bound to do
it for you and plug in +/- 50% to make any assertion laughable, such
as:

>Can we describe "pieces" or segments of the radiator as having proportional
>amount of degrees corresponding to their physical length, when excited with
>particular frequency?

You've left too many things out to agree to more than a rather
insubstantial maybe. If that's sufficient, then there's really no
need to go any further, is there?

Every time I say that you are not applying established concepts and techniques correctly, you twist it to make me say I am denying the validity of the concepts themselves.

For the very last time: the basic concepts are valid; but the way that you are applying them is not. Can you really and truly not see the difference?

Hi Butch

The cebik URL I posted gives you dimensions and values for a full length one.

I'd suggest that since it is such a wide band device terminated in a resistor, choose some arbitary value like 600 ohms, feed it via a balun transformer and see what happens! Take the manufacturers description and photo to work out the wire lengths.

What I am mainly getting at is being such a wideband antenna with resistive loading, the dimensions wont be critical.

Cheers Bob VK2YQA

I have no camp. You are lifting what I say out of context and deleting
important things.

What I say, over and over again, is I can build an inductor in a short
mobile antenna that has essentially equal currents at each end. A
compact loading coil of good design has this type of performance.

The current taper across the inductor is not tied to the number of
"electrical degrees" the inductor "replaces". It is tied to the
distributed capaciatnce of the coil to the outside world in comparison
to the termination impedance at the upper end of the coil.

What "good book"? It would help to see the context.

None of my engineering books use electrical degrees except to describe
overall antenna height or length.

They might say "60 degree top loaded resonant radiator" but they don't
say "60 degree tall radiator 90 degree resonant".

There might be a correct context, but I can't think of one off hand. So
I need an example from a textbook.

> If you stick those verticals (resonant) end to end and horizontal, you get
> shortened dipole, with current distribution equal to 180 degrees or half

The current distribution would not be the same as a half wave, becuase
the antenna is not 1/2 wave long.

> Can we describe "pieces" or segments of the radiator as having proportional
> amount of degrees corresponding to their physical length, when excited with
> particular frequency?

Yes. It works fine for length. It does NOT work for loading inductors,
it does not work for short antennas which have anything form a uniform
distribution to triangular distribution, or any mix between including

curves of various slopes.

A 30 degree tall antenna with base loading simply has power factor correction at the base, provided the inductor is not a significant fraction of a wavelength long. It is a 30 degree base loaded radiator, not a 90 degree antenna. And the inductor is not 60 degrees long.

W8JI and "his camp" are claiming it can't be so, current through the coil
has to be the same or almost the same, with no significant drop across the
loading coil. "

I'm not sure who all you put in W8JI's "camp," but I'm absolutely sure that I've read recent postings by W8JI himself that affirm that there can be significant difference in current between the ends of the loading coil. What I DO see him posting is that if the difference is large, the antenna design is almost certainly suboptimal.

If you want to understand how a loading coil with zero capacitance to the outside world can actually work, I suggest you read the Joseph Boyer article from "Ham Radio" magazine some 28 years ago. Ian White gave a more complete reference to that article in one of his postings in the interminable thread. I'm always happy to ship out a copy of that article for the cost of postage.

Cheers,
Tom

Yuri, you have neglected at least one important unit of measure: namely, the action integral of the 'active antenna' times the current [ampere*degrees].

For simplicity, assume a constant one ampere is flowing in a physical 15 degree antenna. The answer is 15 ampere*degrees. In a true 1/4 wavelength antenna the answer is 90 ampere*degrees. The shortened antenna is [=] a tuned 15 degree antenna NOT a 90 degree antenna!!

In a real shortened antenna, the base current may be assumed, to a first approximation, as constant from the base to the loading coil. If that portion of the antenna is 10 degrees, then 10 ampere*degrees is the action integral.

The current in the top section can be assumed linear from the value at the top of the coil to the tip where I=0. This is a triangle [or a sin function that is close to linear] that can solve to two possible values. The first is based on one ampere exiting the top of the coil and the solution is 1/2*1 ampere*5 degrees = 2.5 ampere degrees. The second is based on a sinusoidal distribution from the tip to the 5 degree point at the top of the coil where the current is 0.087 ampere. [The sin of 5 degrees is 0.087.] So, the action integral is 1/2*0.087 amperes*5 degrees = 0.218 ampere*degrees.

The practical application deals with the efficiency of the antenna. Is that tuned 15 degree long antenna a 12.5 ampere degree antenna; or, is it a 10.218 ampere degree antenna? [That's approximately a difference of 1 dB in antenna performance.]

The discussion here for the past three infinities is: What is happening inside the tuning coil? Is there a change in current amplitude? If so, please explain the physics. Is there no change in current amplitude? If so, please explain the physics.

The coil is physically less than one degree in length, but contains enough wire to be a significant portion of a wavelength. Interwinding capacitance and distributed inductance can make the coil look like a transmission line.

The flux density from each turn in an air core coil construction diverges as one progresses along the coil [the flux density at turn #2 is higher than at turn #60 for example]. Restated, there is a leakage inductance along the coil. The flux density has a propagation time in free space of approximately 0.5E-9 seconds. Is this significant? [I don't think so]

In the tuning coil there exists an interwinding capacitance and a capacitance to "structure" [whatever that is].

In 1958, my college days, we were instructed to ignore the coil and solve the antenna as two separate sections with an infinitesimal gap at the junction. I never liked that model then and I don't like it today! [It still allows two solutions][We were instructed that the current is constant].

So, we have two well entrenched positions: the current does not change in the coil, and, the current changes in the coil. Like World War I, it is trench warfare with much bloodshed [reputation] on both sides.

Due to leakage inductance, I suspect that the current does change within the air core coil but the change is much less than that implied by the simple sin wave distribution [sin 5 degrees] used above.

Below the coil the H field dominates. Above the coil the E field dominates. The transition from E to H occurs across [within] the coil. That leads me to conclude that there is a change of current within the coil.

In any event, the 15 degree antenna is still a 15 degree antenna! The question is: what about that 1 dB difference in the modeling analysis?

This simple engineer is still unconcerned about one dB difference and it's impact on antenna gain. If the science side of this discussion can't agree, then I'll simply continue to operate mobile and not worry if my signal is one dB stronger or weaker at the receiving end of the path!! It is what it is!!

then the web site is doing it's job... it got your attention. you have just one misconception, they are SELLING the antenna, not trying to tell you how to build it. so fork over some cash, probably big cash with fancy components like oxygen free uv resistant litz wire! or just go throw some wire in the air and stick a tuner on it and have fun.

3434. Any good antenna design software

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-24 00:02:53 UTC
From: David <dhuisman@bigpond.net.au>
Message-ID: <NGGUf.15023$dy4.6714@news-server.bigpond.net.au>
Source record: 62395

I am looking for antenna design software.

Initially I purchased EZNEC and downloaded a couple of other programs but realized these are analysis only programs that are great to check performance and optimize once you have a design.

I managed to find a variety of freeware design programs but they were not very extensive (an mostly DOS programs that sometimes crashed my graphics).

My preference is for a Windows based design environment that provides some templates as starting points for a variety of antenna styles (Yagi, LPDA, Verticals). I would like to be able to set up the program with the materials I have available and some performance criteria and it would output element lengths, spacing, suitable matching (or give input impedance etc). I can then enter this design into EZNEC or MMANA to analyse performance.

Thanks in advance if you can point me to suitable software I can purchase.

Regards

David

Thanks guys. I tried the models and they still look poor. Let me explain a bit...

> What is "good" gain?

More than a 3 element yagi.

> What frequency?

Well, I was trying 160, 80 and 40. I have a 300ft support at one point, and a bunch of 100ft trees a good distance away across open fields (maybe 800 feet).

> How high?

Anything up to 300 ft at the feedpoint.

> Try this at 10 MHz. Dimensions in feet.

That antenna almost equals a three element yagi in gain, but the 3 ele yagi has a HPBW of 60 degrees. The V beam has a HPBW of 18 degrees. Not so good. Even if I try two V beams, one inside the other, I can only get 3dB more gain.

I was wondering if I was missing something, because I keep hearing stories about how good big V beams work.

Yes, but you can use an arbitrarily large number of sections, each with a small amount of L and C, and mimic a transmission line to any desired degree, over any frequency range you want. And all with zero physical size in the theoretical case, and arbitrarily small physical size in the practical case. In the limit of an infinite number of sections of vanishingly small L and C each, you arrive at the general equations for a transmission line, valid at all frequencies.

The point I'm trying to make is that you don't need any particular physical size or any particular length of wire to make something that behaves like a transmission line to any degree of accuracy.

Maybe you should ask for files for specific antennas? People probably

> . . .

I believe you're comparing the field strengths from two antennas both driven by the same current. If you drive them with the same power, a more fair comparison, you'll find a negligible difference in field strength. Efficiency is another issue, solely related to losses in the antennas. Without knowing what those losses might be, we can't say anything about the relative efficiency. In practice it'll probably be extremely closely the same also.

and more important to this discussion, you don't need standing waves or antennas. For any given load impedance, it behaves the same way.

It's a shame Cecil misses that point, and thinks it is standing waves that affect the system.

Is this an explanation of the term 'capture area' I hear a lot of hams
use.

regards, Jer

As a 'rule of thumb' the captured signal power in small loops is
proportional to the area enclosed by the loop. Twice the area = twice
the
power (3 dB).

The typical dimensions given for these loops allow them to be used on
either
160M or 80M -- and as you have surmised, the loop can be larger for 160M
only.

I'm sorry I haven't explained this better. If we start with the inductor in, say, the example antenna on Cecil's web page, we see that the magnitude of current at the top of the inductor is less than at the bottom of the inductor. Cecil has promoted various theories about why this happens, mostly involving traveling wave currents and "replacement" of "electrical degrees" of the antenna. He and others have given this as proof that the current at the two ends of an inductor are inherently different, regardless of its physical size. My counter argument goes something like this:

1. If we substitute a lumped component network for the antenna, there are no longer traveling waves -- along the antenna at least -- and no number of "missing electrical length" for the inductor to replace. Or if there is, it's "replacing" the whole antenna of 90 degrees. Yet the currents in and out of the inductor are the same as they were before. I feel this is adequate proof of the invalidity of the "replacement" and traveling wave arguments, since I can reproduce the same results with the same inductor without either an antenna or traveling waves. This is shown in the modified EZNEC file I posted.

2. The argument that currents are inherently different at the ends of an inductor is shown to be false by removing the ground in the model I posted and replacing it with a wire. Doing so makes the currents nearly equal.

3. Arguments have then been raised about the significance of the wire and inductor length, and various theories traveling waves and standing waves within the length of the coil. Let's start with the inductor and no ground, with currents nearly equal at both ends. Now shrink the coil physically by shortening it, changing its diameter, introducing a permeable core, or whatever you want, until you get an inductance that has the same value but is infinitesimal in physical size. For the whole

transition from the original to the lumped coil, you won't see any significant(*) change in terminal characteristics, in its behavior in the circuit, or the behavior of the whole circuit. So I conclude there's no significant electrical difference in any respect between the physical inductor we started with and the infinitesimally small lumped inductor we end up with. And from that I conclude that any explanation for how the original inductor worked must also apply to the lumped one. That's why I keep bringing up the lumped equivalents. We can easily analyze the lumped circuit with elementary techniques; the same techniques are completely adequate to fully analyze the circuit with real inductor and capacitance to ground.

(*) I'm qualifying with "significant" because the real inductor doesn't act *exactly* like a lumped one. For example, the currents at the ends are slightly different due to several effects, and the current at a point along the coil is greater than at either end due to imperfect coupling among turns. But the agreement is close -- very much closer than the alternative theories predict (to the extent that they predict any quantitative result).

>

That's fine, too. Will Cecil's theory explain the behavior of a lumped constant circuit? Or everywhere along the transition between the physical inductor and lumped circuit I described above?

> > The example Cecil posted on his web page was one for
>> which the L could be modeled completely adequately as a lumped L, at
>> least so far as its current input and output properties were concerned.
>
> (if you add to that model, the appropriate lumped capacitors at the
> appropriate places)

No. The inductor itself can be adequately modeled as a lumped inductor without any capacitors at all. When you add ground to the model, you

have to add the equivalent shunt C to the lumped model. The C isn't a property of the inductor itself; it's the capacitance between the inductor and ground. This difference is the source of confusion and misunderstanding about the current -- the current we see at the top of the inductor is the current exiting the inductor minus the current going via the shunt C to ground. It's not due to a property of the inductor itself. We're seeing the *network* current, not the inductor current. Removing the ground lets us see the inductor current by itself.

>
>> Being a significant fraction of the antenna's total length, it of
>> course does a substantial amount of radiating which a lumped model
>> does not.
> Another reason to avoid that model, unless you are just looking for the
> least amount of math to get an approximation. But computation has
> gotten very cheap.

The problem is that it obscures what's happening -- we can no longer easily tell which effects are due to the radiation, which are due to the capacitance, and which are inherent properties of inductance unless we separately analyze separate simplified circuits (as I did with EZNEC). And that's really what the whole disagreement has been about. Effects due to shunt capacitance have been claimed to be inherent properties of all inductors, and elaborately crafted theories developed to attempt to explain it. If all you want is numbers, they're plenty easy to get without the programmer needing to have the slightest understanding of what's happening. And he will have learned nothing he can apply to other situations.

Distributed analysis is just fine, but it should predict the same coil currents with the antenna replaced by lumped components. And it should predict nearly equal currents in the inductor ends when ground is removed. And it should predict the same results when the coil and the shunt C to ground are replaced by lumped components. Because that's what really happens. My simplified lumped component analysis does all this. A rigorous solution of the fundamental equations for distributed networks does this also -- EZNEC does its calculations with just such equations and reaches the correct conclusions. But I don't believe that Cecil's theories and methods provide the correct results in all these cases.

> . . .

> A lumped inductor has no stray capacitance. Those also have to be added
> to the model, before the effect would mimic the real coil (neglecting
> radiation).

By removing the ground in the model on my web site, I found that a lumped inductor mimics the real inductor very well without any C. Of course, to model an inductor close to ground requires adding a shunt C. Modeling an inductor connected to a resistor would require adding a resistor to the model. But we shouldn't confuse what the inductor is contributing to the performance of the circuit with what the other

components are. And that confusion has been common here.

> . . .

> But in the real world, the capacitance is always there. It varies,
> depending on the location of the coil, but it never approaches zero.

It can get insignificantly small, as in the modified model. But that's really beside the point. The point is that the shunt C isn't an inherent property of the inductor, and the current difference between the top and bottom of an electrically short coil is due to the current flowing through the external shunt C, however big or small it is. It's not due to waves bouncing around inside the coil or painstakingly winding their way turn by turn from one end to the other, or by any inherent and fixed property of the inductor or the antenna it's connected to.

Something does not make sense!!

There HAS to be a difference in gain between two antennas IF their HPBW
are different. Isn't it the case that the narrower beam has to have
higher gain?

No.

First problem, the V beam has more loss. Probably because of the very long current path through conductors.

Second problem, large sidelobes that rob power

The beamwidth of high gain is much narrower than a Yagi, but the thing has no more gain.

It looks like a simple antenna, has a good reputation, but it doesn't look very useful for anything. Unless there is a combination I'm missing.

Cecil,

You can be the master of brevity, at least when it serves your purposes. You might take a look at the entire sentence rather than clip out the portion that sets the context.

"Certainly these consolidating functions are useful for a general overview, but how can you learn anything about the details of a complex system by averaging and netting?"

By the way, "steady-state analysis" has nothing whatsoever to do with averaging. Steady-state simply means the system does not have a defined starting time. There are no remaining startup transients. It cannot be determined whether operation started one second ago or one year ago. Steady-state does not mean DC, averaged, or RMS.

73,
Gene

FWIW, if you can't model the antenna and change the design, try
looking for someone else's design similar enough to make the change.

You may just try reducing the number of elements according to your
desired maximum length without much consequence.

Good luck

I was just reading about them in the antenna handbook. The v-beam is
better than a dipole and is directional, but the same wire bent
half-way out to make a rombic seems to add more gain. you might look
into it.

Do you have a break-down of the assembly of the rotor? If there are
no bearings when held upside down, you may damage the rotor by hanging
it that way.

Don't know about some of the newer inexpensive TV type rotors, but my old
AR-40 has lubricated ball bearings running in a groove. Don't know if
running that upside down would
be a problem or not. I believe I'd work out an attic floor mount that would
allow it to operate in the normal orientation. If cost is not a priority,
however, running it upside down might make for an interesting experiment.

I don't think it will work right. There will be no force on the ball
bearings at all, they will just be floating. All the friction will show up
on whatever is on the other end of the shaft that keeps the unit from
falling apart.

I've never worked with a Vee antenna. But, while stationed at Hill AFB, Utah we used two of them back to back to make a Rhombic :-) to support the South East Asia phone patch nets during the Vietnam conflict. Fixed point to point communication [We had an LP that was used for stateside COMMs]

My understanding is that a narrow beam is formed along the axis [centerline] of the Vee. In a standing wave antenna, the beam is bi-directional. In a terminated antenna, traveling wave, the pattern is unidirectional. The narrow beam width reduces interference from undesired directions.

Total wavelength and included angle have significant impact on performance.

I wonder of Roy can add constructively to this discussion regarding apparent low gain.

That's all nonsense, including the Sommer site!!

Capture area, more correctly called effective aperture, and gain has nothing directly to do with physical area of an antenna. It is strictly a function of the operating wavelength and gain of the antenna.

If I double the size of an antenna the capture area (effective aperture) might increase, decrease, or stay the same.

If I have a small loop and it has zero loss, the capure area is effectively very large.

If I have a full size dipole and add enough loss resistance, capture area is very small.

Capture area is generally an excuse people make to justify using a larger antenna, even if the antenna does not work as nearly as well. "My quad works great for receiving because it has large capture area." Nonsense. If it has the same gain as a Yagi on the same band, it has exactly the same capture area. If it has less gain than a Yagi (which many quads do, hence the reason you don't see them in contest stations) it has less capture area.

I'd be ashamed if I was selling antennas and did not understand what capture area was.

Howard,

The polarization of a quad fed at the bottom of a diamond is
horizontal.

The polarization of a quad fed on the point of the side is vertical.

The polarity of the feedpoint changes 14,000,000 times if you excite it
on 14MHz for one second no matter where it is fed, but the polarization
only changes when you move the feedpoint to a new location. :-)

That's a nice feature of a quad. By changing feedpoint loaction you can
change polarization.

Message-ID: <0aXUf.6445$x94.4064@newsread1.news.pas.earthlink.net>
Source record: 62326

I was browsing through Antennas by Kraus, second ed., looking for something that might explain how two antennas separated by a distance D would have a resolution as the same as an antenna of size D, and hit upon some methods for computing radiation patterns. I'm not all that familiar with the methodology, but think it might be worthwhile exploring.

I'm not all that knowledgeable about antenna theory, but was stumped by the introduction of antenna phase. He computes the patterns for several pairs of isotropic antennas separated by a distance d. There are several cases, which involve fixed or differences in phase and amplitude he considers, Chap. 4, sect. 4.2. Can anyone make the idea of phase dependency for an antenna, particularly an isotropic antenna (or whatever), a little more practical or real? Early on he talks about the phase delta being a function of (theta, phi) according to a typical Kraus 3-D view of this material. A nice abstraction, but I need something a little more concrete*.

Of course, maybe my statement above about D is simpler to *prove* (not hand wave) than wading through this material.

* I just noticed section 3-17 has some material on phase. Maybe that'll work.

Tom is correct. Vee beams and rhombics have horrible sidelobes that
make them in my estimation highly overrated. The vee is not completely
bi-directional, a couple of dB FB is not uncommon. A vee, just like a
rhombic can be terminated to increase the FB. If the legs are long
enough it -is- a traveling-wave antenna and is somewhat
self-terminating.

The claim for broadband gain is also suspect. There are optimum
parameters that are not frequency independent

Of course I can't fault VK5MC's three-stack rhombic that gave me my
two-meter WAC :-)

Hi Wayne,

Not having that reference in front of me, I will wing what appears to
be the topic at hand.

When you have two detectors that are resolving one source, or when you
have two sources that are impinging on one detector; then you have the
makings of triangulation. I hope that much of the 3-nature of this
problem reduced to its simplest terms is apparent.

For the sake of discussion, we can call them X, Y, and A; where the
pairing of the X-Y are the two that are similar and A is the odd one
out.

The distance XA can be expressed in meters, phase, or time. Similarly
the distance YA can be expressed in meters, phase, or time. Going
further, the distance XY can be expressed in meters, phase, or time.
The units of meters, phase, and time are all fungible. That means
they substitute equally as long as you take care to use the same units
throughout. Whenever you read distance, think phase instead, or
convert to phase. Even though they are the same, meters or seconds
just aren't as useful in our discussion.

When you mathematically combine these distances, you can precisely
described the signal strength at any point (including those points not
described as A, X, or Y).

Take a simple DC example of X being a positive charge of 1, and Y
being a negative charge of 1. If A lies on a line that is between the
two, and is perpendicular to their axis, then A will sense a
difference of 0. If you move A out of this perpendicular plane, it
will encounter non-zero fields because the contribution of the two
charges do not cancel fully. This moving of A throughout space will
map out what is called "the dipole moment" which looks like a figure
8.

Extend this analogy to the RF by simply stating that X and Y are 180ï¿½ out of phase. In the first position of A, it will still resolve a 0 difference (the two paths XA and YA are equal by definition and the phase is bucking - net 0 signal). Move A out of its perpendicular plane and the two path distances will be non equal. A small signal will emerge from the combination of the two XY signals.

Push this analogy a little more by slightly changing the phase of either X or Y. A at its original position will now perceive two out of phase signals, but their phase difference will yield a small signal response.

If you move A to the correct spot (out of the plane of perpendicularity), you may find that null again. Thus THAT null occupies a region that satisfies the combination of a resultant phase of 180ï¿½. This is accomplished by shifting the
XA distance - YA distance
expressed in terms of phase such that when added to the XY phase yields 180ï¿½.

This last operation is called Beam Steering, you moved the null in 3-space using only phase shift at one X or Y. You could have as easily moved X or Y too to accomplish nearly the same result. You can also steer the point of maximum (the anti-null) - and did. If you flip the roles of the source and detector, you have source location.

You can also achieve some steering through amplitude shifts of XY, but this is bringing more complexity to the topic. Suffice it to say that this math of combining amplitudes and phases for Beam Steering or source triangulation applies equally to source/detectors as it does to detector/sources.

With two sources/detectors XY, there are ambiguous results. The nulls occupy two regions, not one. If you add a non co-planar third source/detector XYZ, then you can resolve without ambiguity (or perhaps less). This is still a matter of combining distances to A in terms of meters, time, or phase.

The Method of Moments used by NEC is simply (ironically, more complex) the substitution of many, many sources in the place of segments of an antenna's structure. That is, a MOM dipole is composed of perhaps a dozen infinitesimal radiators in a line, with each having a phase shifted signal of a different amplitude. Their combination at a distance gives us that "Dipole Moment" (figure 8 field) that is so familiar. The utility of the MOM is you can shape up to several hundred or thousand sources into a complex geometry to present a more complex field resultant. NEC is merely a phase/distance/time combining engine that moves A throughout space to build a response map.

To this last point, it reveals a truism:
The entire radiator emits, not just a portion of it.

The "entire" radiator consists of the antenna, its counterpoise, its loading, and sometimes its feedline.

Another truism arises:
The entire radiator emits in all directions (think spherically).

Remote detectors are illuminated by a radiator no matter where they might lie. That they may not sense this illumination is merely the consequence of overlapping, bucking phases.

One might be tempted to say that for the classic dipole, there is no radiation off the ends. The second truism negates that. You need only flip the phase of one half of the dipole to make it endfire (yes, easier said than done). In the first, classic sense both sides illuminate far colinear objects destructively. In the second sense both sides illuminate far colinear objects constructively.

Better to s that the vertical will put out more of it's energy at low angles. That makes a difference.

Another thing to consider is that the vertical will take a whole lot longer to install than the dipole. Those radials can be a real pain in the back!

The way my thinking has been shifting recently, I would suggest that people - a lot of people - think of the radiation pattern of an antenna as some sort of narrow blob that shoots off the thing at the "maximum angle". Trouble is, all antennas radiate at all angles. Some just better than others. Before condemning a dipole as not usable for DX because of its radiation angle, we should probably compare it to the angle of that vertical. Then look at just how many db difference there is between the two (all else being equal).

And of course, as I have been finding out, which one does best at any given moment (let's define best as the highest signal level at the receiver) is going to change from moment to moment. I haven't gone to transmitting differences yet

http://wireless.gumph.org/content/4/3/011-mini-wireless-antenna.html

The author calls it a sector antenna but I'm sure I've seen it in ham applications but with another name.

Also, can anyone quote me a dbi gain figure (@2.4ghz) for this?

Thanks for the help!

That's a collinear array, of a type sometimes called a Franklin antenna.

It's very hard to estimate the gain, because even when constructed perfectly, the velocity factor of the coax prevents the inside and outside from both being the ideal length. And at that frequency, very small imperfections in building technique can have a major impact on the gain. But it should be a fun project and it might give noticeable gain over a quarter wave monopole.

Are you recommending it?

Is the following statement from the page correct?

"Note: Antenna B has only half the capture area of antenna A and is
therefore able to "catch" only 50 percent of the electromagnetic
field; e.g., 50mV, compared to 100 mV/50 Ohms. This means 6dB less
gain for antenna B in comparison to antenna A."

I agree up till you add, "regardless of physical size". I have seen
him talk only about large air core space wound coils. I came to the
discussion late, but this is what I have seen.

> My counter argument goes

But what is the need for such an argument? Just to prove that lumped
component networks can model real, distributed things? I get that.
As I see Cecil's point (and I hate to say this with him absent), it is
that real, large coils with all their poor turns coupling and stray
capacitance both turn to turn and more important, to ground, take a
lot of those lumped components to model, accurately, but only their
own self, described by distributed network concepts to model, accurately.

> 2. The argument that currents are inherently different at the ends of an

But the ground is there, in the application under discussion. All
components act differently if you connect them to something else.
This coil is connected to ground by its capacitance.

Distributed network theory includes the possibility of lumped
components, it is just not limited to them.

(snip)
>> (if you add to that model, the appropriate lumped capacitors at the
>> appropriate places)
>
>
> No. The inductor itself can be adequately modeled as a lumped inductor
> without any capacitors at all.

Not if it is located in close proximity to ground, as this coil in
question is located. It does not act like any kind of pure
inductance, but as a network that contains some inductance and also
some other effects.

> When you add ground to the model, you
> have to add the equivalent shunt C to the lumped model. The C isn't a
> property of the inductor itself; it's the capacitance between the
> inductor and ground.

That is a very strange statement to my mind. Stray capacitance is an
unavoidable effect that any real inductor in any real application will
have as a result of it having non zero size. A thing made of wire
that takes up space has inductive character and capacitive character,
and transmission line character, and loss, all rolled into one. You
can set the situation up that it finds itself in, is that some of
those properties not very significant, but that are all part of the
effect of a real, physical inductor. I don't understand why you keep
pretending that these non ideal effects are the fault of something
else. They are a result of the device taking up space and being made
of metal.

> This difference is the source of confusion and

I agree. But a large, air core, spaced turn coil is a network, not a
pure inductance. This is just reality.

> Removing the ground lets us see the inductor current by itself.

Or, emphasizes that particular aspect of its nature.

Hello, Richard.

Well, you certainly got the gist, without seeing the book, of the underlying problem I was having with phase, time, and distance. That was a helpful paradigm shift for me. I leanred a new word in the process, fungible. It was well used. I had thought about the sense of all this with respect to direction finding, but you added some extras.

Ultimately, I'm trying to comprehend, via a proof, that two receivers separated by a distance D can act as though they are a single receiver of size D. Perhaps it can be done by simply considering the Young double slit experiment. It bothers me that the idea is passed along without ever proving it. Maybe the proof is trivial.

Cecil's point is rather obscure, but as I read it Cecil thinks the ONLY
way to model a loaded antenna is through reflected wave theory.

As I understand what Cecil writes, he seems to be saying if we use a
current meter we cannot measure current. If we look at an inductor's
properties he seems to say they change in the presence of standing
waves. He also seems to be saying a loading inductor replaces a certain
number of electrical degrees through some reflection property.

What most others seem to be saying is an inductor is an inductor. It
behaves the same way and has the same characteristics no matter how it
is used, so long as we don't change the displacement currents by
varying capacitive coupling to surroundings.

That is where the difference is.

I can easily build a loading coil that has no appreciable change in
current from end-to-end. My measurements of typical loading coils shows
it is the ratio of load (termination) impedance to capacitance to the
outside world that controls any difference in current, and not the
"electrical degrees" the coil replaces. It is also not the reflected
waves that cause the unequal currents, but rather the fact the inductor
has distributed capacitance to earth or other objects besides the coil.

Capacitance from the coil to itself won't cause these problems. The
change in phase of current at each end of a coil would depend heavily
on stray C of the coil to the outside world as compared to reactance of
the coil, and it would also depend on less than perfect flux linkage
across the inductor.

I measured a typical inductor and found it did have more phase delay in
current at each terminal than the actual spatial length of the coil
form would indicate. I measured a delay about equal to double the
length of the 10 inch coil form length. If the inductor was perfect,
the delay would be about equal to light speed across the length of the
inductor form.

The only thing in all of this I can't find agreement with is what Cecil is saying. I'm not disputing currebnt can be different, and phase can be different. What I am disputing are Cecil's claims that an inductor behaves differently in an antenna than in a lumped system that represents the antenna, and that the cause of inequality in currents or phase delay is caused by reflected waves and cannot be understood without applying reflected wave theory.

In my experience, either lumped circuits or reflected waves will work IF applied correctly.

This is my take of the disagreement.

I hope this question isn't taken the wrong way, but why would you want
a similar site? That one is terrible for accuracy. The poor fellow who
wrote that page doesn't even know what capture area is.

Wouldn't it be better to find a totally different type of site, one
that at least has some technical accuracy?

Hi John,

One of the problems is the thread discussion is freely mixed with
practical observations and theoretical arguments - these can clash,
especially when mixed indiscriminately to prove one point.

First, several years ago, came the shocking observation that the
current into a coil is not the same as the current out of it.
Somewhere along the debate, this practical measurement was then
expressed to be in conflict with Kirchhoff's theories. However,
Kirchhoff's current law is for currents into and out of the same point
intersection, not component. The association with a point is found in
that the "lumped" inductance is a dimensionless load. The association
with Kirchhoff was strained to fit the load to then condemn the load
instead of simply rejecting that failed model and using the correct
one.

The problem came from incorrectly specifying the coil in EZNEC which
offers a coil generator (inductor) in the wires table as well as a
coil specification (inductance) in the loads table. This shocking
difference between model and observation would have been easily
resolved by simply using the coil generator (inductor) in place of the
lumped equivalent (inductance).

How do you know when you've made a mistake in application? You do two
designs and compare each to what nature provides. You discard the
model that does not conform to nature.

Want to know what the difference is between the two (the good and the
bad design) at the far receiver? ï¿½.32dB Hence the name of my thread
"Current through coils - BFD."

...snip

>But the ground is there, in the application under discussion. All
>components act differently if you connect them to something else.

>This coil is connected to ground by its capacitance.

Roy's point is that the proposed "theory," as Ian has also pointed out, has to correctly answer all scenarios, not just one. We don't have enough shelf space in libraries that prove the resistance of each resistor constructed - one formula does quite well for 99.999% of them, and a couple more formulas for those that don't (and those new formulas will give the same answer for the first 99.999% as well).

>> When you add ground to the model, you
>> have to add the equivalent shunt C to the lumped model. The C isn't a
>> property of the inductor itself; it's the capacitance between the
>> inductor and ground.
>
>That is a very strange statement to my mind. Stray capacitance is an
>unavoidable effect that any real inductor in any real application will
>have as a result of it having non zero size.

You are mixing an observational fact with a theoretical statement. The lumped model contains ONLY inductance, to make it conform to nature, as Roy is doing here, you have to add in all the nasty bits.

OR

Build a helix (inductor) in the wires table.

>A thing made of wire
>that takes up space has inductive character and capacitive character,
>and transmission line character, and loss, all rolled into one.

These are all properties that reside in a helix (inductor) constructed in the wires table. Some of these properties (like inductance) also reside in the load table, but not the capacitance to earth. If it matters, it is up to you to make the correct choice.

...snip

Well, the rest was more conflict between theory and practice that is and has been resolvable for a long time. Even the conflict is separable. For those who persist in making poor choices, they will always have either a problem with a model, or the genesis of a new theory, or rattle on beyond 500 posts - sometimes all three.

(as usual, I'm in great need)

I have great problems in trying to post a photo/webpage to the group to help identify and discover dimentions to the "Wideband Folded Loop" that is somewhat described in the artical by RF-Systems Inc.

Cecil, if you would do a google search on this statement "WFL Folded Loop Antenna", it will bring up the aformentioned artical and photograph.

Upon printing the artical out, you will note that the web site is posted in the lower left hand of the page as is normal, however, if you enter that site it will send you to some off the wall site having nothing to do with antennas.

Now, grab your wireless laptop, hop on your hog and enjoy your hunt for my benefit.

What information are you looking for, capture area or effective height? Capture area determines how many watts you'll get into a conjugately matched load connected to the antenna. Effective height determines how many volts you'll get from an open circuited antenna. The two aren't directly related. For more information about the two topics, do a groups.google.com search for postings I've made on those topics in this newsgroup.

As I've posted here quite a number of times before, the capture area of a lossless infinitesimally short dipole is very nearly as great as that of a half wave dipole, in their most favored directions. (The difference is about 10%, and it's due to the slight pattern shape difference caused by different current distributions). So except for loss the capture area of a ferrite rod antenna is within 10% of that of a dipole. But loss in a ferrite rod antenna will reduce the capture area considerably. If you're interested in knowing how much power you can get from a ferrite rod, then, what you need to know is its efficiency, which is a function of wire length, number of turns, and the antenna feedpoint impedance. I don't have the time right now to work it out for you.

The effective height of a ferrite rod antenna is approximately:

(2 * pi * mueff * N * A) / lambda

where

mueff = effective relative permeability of the rod (mainly a function of rod length)
N = number of turns
A = rod cross sectional area
lambda = wavelength

Hi Wayne,

The two receivers/antennas is called "synthetic aperture." You can
observe the same thing with one antenna that is moving, we commonly
call it "picket fencing." This effect is due to reflections and
direct signals interfering constructively and destructively as you
move through the interference field. The math for that alone is found
in "Fresnel loss."

The Young double slit IS the proof in that it contains all the math
you need. It contains two transcendental operations (sin or cos) as
many thetas as there are phases and distances, some magnitude
information, and the result pops out at you.

In fact, the math is all the same for all of these effects.

Does that include an antenna that has been brought to resonance with
an appropriate capacitive load?

So if a very small rod antenna had a lossless core that could handle
any flux level, and was wound with superconductor, it could couple
into the same volume of space as a 1/2 wave dipole? Amazing.

I can apply this formula directory to what I am experimenting with,
except that I have to approximate mueff. I am making the rod by
stacking ferrite beads, with various gaps between them. Can I
approximate mueff by taking the ratio of coil inductance with and
without the rod?

And, what if the rod area is not constant all along the rod? Since my
rods are assembled from pieces, I have a lot of freedom in this direction.

3491. Re: V Beam, do they work?

Dear Tom:

It appears that you are investigating a slopping, V-beam with a feed point at about 90 meters and an operating frequency of, say, 1.82 MHz. When first used some 80 years ago, V-beams were horizontal (or, alternatively, entirely in a vertical plane). Two more 90 meter poles are not likely to be in the picture.

The good news is that you are apparently interested in a narrow range of frequencies. That is good news because aligning the lobes with their changing polarization and orientation over a significant bandwidth is like composing something to compete with Mozart.

Even using one frequency, it is a bear to get a slopping V to do one's bidding. I would limit lengths to integer multiples of 0.5L that could fit your farm. I would optimize a single, end fed wire (over ground) and in the process find a narrow range of lengths that look promising and that fit your site. Then add, and drive, the second wire. Iteration is called for. I would use a figure of merit that is the gain at a TOA of something like 30 degrees.

Kraus, even in the first edition, presents several approximate equations to optimize a horizontal rhombic. They may give a little guidance. I think I read a Technical Report in the mid 60s on measurements of a sloping V put out by either NBS or ESSA. I seem not able to put my finger on it just now.

As mentioned, the difficulty with sloping wires is finding a "good" bore-site addition of fields from the two wires when those fields are, to a first approximation, in the shape of cones with changing polarization. It is more easy with horizontal wires.

If I live long enough to retire from teaching, this is a type of project that would be interesting to investigate. But I only have 42 years in and my good wife is certain that I could not stand the pace of retirement. Do let us know what you come up with. Good luck.

73, Mac N8TT

Two side notes: My friend, HS and University classmate, and great DXer W8TWA has used a set of sloping V-beams on HF to good effect. -- As you know better than almost anyone, one needs a height in the neighborhood of 2L to get serious signals from a horizontally polarized antenna at the lower TOAs used for DX. You may find that your best sloping V-beam has a strong vertically polarized component in the main beam.

No. "Open circuited" means that there's nothing connected across the feedpoint.

> . . .
> So if a very small rod antenna had a lossless core that could handle any
> flux level, and was wound with superconductor, it could couple into the
> same volume of space as a 1/2 wave dipole? Amazing.

Yes, exactly the same volume of space, although capture area isn't a measure of this. Capture area is an area, not a volume, and it's different in all directions, just like gain. In fact, there's a 1:1 correspondence between capture area and gain, they're just different ways of expressing the same thing. In the absence of loss, all the power applied to *any* antenna will radiate, so the integral of the power density over all directions is the same for all lossless antennas -- the integral of the power density will equal the applied power, since there's no dissipation (and in the far field the power density is simply E^2 / Z0 = H^2 * Z0 where Z0 is the impedance of free space and E and H are the electric and magnetic field strengths respectively). The reciprocal of this principle is that the integral of capture areas in all directions (what you're calling the "volume" the antenna is "coupling" to) is the same for all lossless antennas.

But more directly to the point, your tiny theoretical rod antenna would have a gain of about 0.45 dB less than a half wave dipole, and its capture area would be correspondingly smaller -- about 10%. This is assuming you're looking in the best direction for each antenna. Because the total radiated power or integral of the capture areas must be the same for the two antennas, this means that the tiny antenna has to have more gain or capture area than the dipole in some other directions. And indeed it does -- the tiny antenna has slightly fatter lobes than the half wave dipole. This is a good experiment to run with EZNEC or NEC-2. The EZNEC demo is adequate. Use free space, set wire loss to zero, and compare the gains and patterns of a half wave dipole to a very short one. The Average Gain tells you the ratio of total radiated power to input power, and it should equal one if the program is doing its

calculations correctly.

Of course it is not.

The article seems based on some typical misconceptions about Capture Area and the suggestion that you can run a ruler over a dipole (loaded or otherwise) to measure up and calculate the capture area is nonsense.

I wonder if that is how Somner derive the gain figures that they publish for their antennas. (Gain is related to Capture Area, and if they don't understand Capture Area, do they understand Gain?)

I want to thank you for the efforts and patience with me. I hope my insight into the operation of large air core inductors has improved because of it. Please do not think that I am taking up a defense of everything Cecil thinks (since I am sure I don't know what that is, anyway), but just found this technical discussion stimulating. It isn't often I get to talk with such experienced people without getting dismissed or ignored. It has been useful to me. I can't think of a better compliment to offer.

3497. Re: Current through coils

Newsgroup: rec.radio.amateur.antenna

Source record: 62359

Tom, the W8JI one, wrote, among other things,
"Capacitance from the coil to itself won't cause these problems. The change in phase of current at each end of a coil would depend heavily on stray C of the coil to the outside world as compared to reactance of the coil, and it would also depend on less than perfect flux linkage across the inductor."

I've lost track of exactly what "these problems" are, but I was wondering about the "and it would also depend on less than perfect flux linkage across the inductor" part. To help resolve that, I did a Spice simulation; I modelled a transmission line with ten "L" sections cascaded. Each was 1uH series, followed by 100pF shunt to ground. I put a 100 ohm load on one end and fed the other end with a 2.5MHz sine wave with 100 ohms source resistance. Sqrt(LC) is 10 nanoseconds per section, so I expect 100 nanoseconds total delay, or 90 degrees at 2.5MHz. That's what I saw. Then I added unity coupling among all the coils, and to keep the same net inductance, I decreased each inductor to 100nH. The result was STILL very close to a 90 degree phase shift, with a small loss in amplitude. In each case, the current in each successive inductor shifts phase by about 1/10 the total. Although the simulation is less than a perfect match to a completely distributed system with perfect flux linkage (and just how you do that I'm not quite sure anyway...), but it's close enough to convince me that perfect flux linkage would not prevent behaviour like a transmission line, given the requisite distributed capacitance.

(That was from a "transient" simulation, 10usec after startup so it should be essentially steady-state; but I'll probably play with an AC sweep of both cases as I find time.)

Cheers,
Tom

But I can design the coil to be self resonant or not, just by adjusting the surface area of the wire, or the spacing. It is non intuitive that if I peak the coil this way, and obtain more voltage, it is a different case than if I peak the coil with cable capacitance, or an additional capacitor. I guess I really don't comprehend the point of this value.

(Snip excellent review of basic lossless radiator. Thank you.)

Well, now I can calculate the effective height of my antennas, even
though I am not sure what it has to do with height.

I am also experimenting with designs that do not necessarily have a
small, coil, close to the rod. (My interest in the discussion of
extended coils is showing.) One of the possibilities that shows a
significant increase in tuned Q is an hour glass shaped coil (small
diameter in the center, but sweeping to a larger diameter at the
ends). I have been asked to try putting a rod through the center of a
flat spiral coil. It seems to me that, at some extreme, the above
formula will fail, because it assumes that essentially all the signal
energy exiting the coil was collected by the rod, and that the signal
the coil would collect by itself would be insignificant. But if my
coils get large enough, they become loop antennas in their own right,
and the rod, though it may have a significant length and area, is only
a part of what is happening. In other words, the mueff can get pretty
small, even though the rod has significant dimensions. I guess, what
I am asking are what assumptions about coil dimensions (that are not
explicitly referenced in the formula) are being made in the above formula?

Caution, ancient history: In the early 1970's, I hung a rotor upside down in an attic. It only had a 4-bay bowtie UHF TV antenna on it, but it was rotated at least daily and never gave me a bit of trouble in about two years.

No, I don't recall the brand but it was the kind with the wirewound resistor and wiper for position information. Alliance may have been the company that did it that way.

Sorry, I don't understand what you're "peaking" and how. I believe that the formula I gave assumes that the coil is well below self resonance where the shunt capacitance is negligible. It won't be valid near self resonance, if that's what you mean.

> . . .
>
> Well, now I can calculate the effective height of my antennas, even

Do a groups.google.com search of this newsgroup for my postings containing "effective height" or "effective length" -- I posted quite a bit about it not long ago.

I'm sorry, I don't know. The reference it came from doesn't say. It in
turn references Laurent, H.J. and Carvalho, C.A.B., "Ferrite Antennas
for AM Broadcast Receivers", an application note from Bendix
Corporation. That app note, if you can find it, might or might not tell.
I'm sure it's not valid anywhere near self resonance, though.

Your concept of signal energy getting collected separately by the rod
and the coil, or exiting the coil and being collected by the rod doesn't
fit at all with what I know of the behavior of electromagnetic fields,
so I won't even try to comment on that aspect or the conclusions
resulting from it. Maybe it makes sense to Cecil or art -- they seem to
view things in a different way.

Thanks Tom,

That's very interesting. My thought is the difference in
phase-of-current at each of the inductor would be affected by mutual
coupling, with perfect coupling preventing phase differences in
current, but maybe that is shortsighted.

I'll have to think about that a while and how it might affect what I am
saying.

The phase shift in degrees, along a coil or any other sort of
transmission line, is fixed rigidly by its physical dimensions and
test frequency.

Phase shift is entirely independent of the way it is used, the circuit
it is in and the circuit currents which flow.

Butch, it's a folded-up length of folded-dipole sort-of with a
dummy-load/power-absorber in the center. RTMC for the disclaimers.
They're there, believe me.

To play with something like it more easily and inexpensively, attach a piece
of coax to your rig, put a dummy load at the far end, and connect a random
length of wire to the center conductor of the coax, at the dummy load. You
could connect a similar length of wire to the outer coax conductor . . . .
maybe a total of 7.5M of wire in your new terminated dipole ;o)

Coils and transmission lines yet again.

For given coil dimensions, program TRANCOIL calculates numerical values for the line's primary constants Inductance, Capacitance and Resistance including radiation resistance.

Also the secondary constants of Characteristic Impedance Zo, Phase-shift, Velocity Factor and Attenuation.

Resonant frequencies and feedpoint impedance versus frequency are also calculated should the coil be used as an antenna.

Minor details such as wire length and wire gauge are included.

Input parameters can be varied from the keyboard and behaviour of the coil observed versus frequency and dimensions.

Download TRANCOIL in a few seconds from website below and run immediately.

Participants in the recent newsgroup marathon will be able to see and understand more clearly what it is they have been waffling about.

3506. capacity hat antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-25 13:38:17 UTC
From: Buck <not@this.time>
Message-ID: <5oca22pqul1g15ua8sdu0oem5ebg1n2gr7@4ax.com>
Source record: 62367

(My information for this comes from a number of websites including commercial antenna sites. Needless to say, the accuracy of any information, especially that of commercial sites is suspect.)

I have been reading about reduced size antennas using capacity hats instead of, or in addition to, inductor loading. Most sites claim that capacity hats reduce size with much less (or no) signal loss compared to a full size antenna. At least one site claims a vertical 1/4 dipole using cap-hats has gain over a 1/4 vertical ground plane. The consensus seems to be that size for size, the antenna shortened by capacity hats has less loss than the same size antenna shortened by inductors as per http://www.sommerantennas.com/gain.html (taken from another thread in this newsgroup.)

Some claims are that the capacity hat antennas have equal signal strength to their full-sized counterparts.

My research, thus far, my theory is:

1) any shortened antenna will have some loss compared to its full-sized counterpart. (i.e. an 80 meter dipole shortened by one foot using capacity hats will not be as efficient as the full length version, even though one might be hard pressed to find the instrument that could measure it.)

2) antennas shortened with capacity hats have less loss than those shortened by inductors

3) capacity hat antennas exhibit slightly more bandwidth than inductor loaded antennas

4) given equal length, a cap-hat vertical dipole will exhibit equal, (or according to some sites, greater) signal strength to a vertical monopole either reduced or full-size.

Size Loss vs efficiency of a cap-hat dipole.

Assuming my first point of theory is correct, there must be a point in which the reduced size of a dipole using only capacity hats is noticeable. Continued reduction finds additional noticeable points of loss.

What I would like to know is approximately where those points might be so the 'value' of a cap-hat dipole antenna can be determined given some acceptable size or loss.

An example might be I have 25 feet of antenna pole. I can build an antenna with what I have. However, it may be that for ten more feet

of pole, I can have a much better signal. Should I use what I have, or order the additional ten feet of aluminum?

Another example would be to estimate the maximum power I can run on 60 meters using a given length antenna. If a 1/4 wave dipole will radiate almost as effectively as a 1/2 wave, then I would not worry about adding the extra 5 or ten watts I would need to max the ERP out, but if the loss were significant, I would know I can leave my radio on full power (100 watts) without committing a violation.

Thank you for your thoughts.

Buck,

First, that Sommer antenna site is terrible. There just isn't any other way to say it. Virtually nothing on that page is truthful in any way. I actually thought it was an April 1st joke at first.
So toss that info out.

> My research, thus far, my theory is:
>

All other things being constant, if you starting end loading a 1/4 wl vertical antenna with a hat it would start having some gain. The gain might not be useful or important, but it would work that way.

I suggest you read:

http://www.w8ji.com/radiation_and_fields.htm

and the link to

http://www.w8ji.com/radiation_resistance.htm

Actually you could have a shorter antenna with more gain. It is possible, depending on current distribution and loss resistance distribution.

> 2) antennas shortened with capacity hats have less loss than those
> shortened by inductors

Probably true, but not always true..

> 3) capacity hat antennas exhibit slightly more bandwidth than inductor
> loaded antennas

It's more complex than that, but that's probably true in nearly all cases. They can have significantly more bandwidth in some cases.

> 4) given equal length, a cap-hat vertical dipole will exhibit equal,
> (or according to some sites, greater) signal strength to a vertical
> monopole either reduced or full-size.

Again it depends on the system. Vertical dipoles open a HUGE can of worms. Most of the problems surround feeding the antenna and not having the feedline couple to the radiator.

Also, with a good ground system and a given overall height radiator and given loading system, a Marconi has higher efficiency than a vertical dipole.

Some of the very worse verticals around are the "no ground half-wave" antennas, and some of those profess to have high efficiency. If amateur radio antennas were watched and protected like other consumer products, more than half the manufacturers would be sitting in jail for fraud.

It is a complex answer with many "maybes" and "if" statements. There isn't any exact cut-off point.

Modeling antenna will help you understand what happens. If you want to read, stay away from antenna manufacturer and off-beat amateur publications and go to peer reviewed textbooks. You might try Antenna and Transmission Lines by John Kuecken (I attended several of his classes back in the 70's) or the Antenna Engineering Handbook by Jasik.

Jasik's book would be available in good technical libraries and Kuecken book was reprinted by MFJ Enterprises.

More important than anything, you might learn how to model antennas in something like Eznec.

If you want to see what a joke most antenna manufacturer claims are, get a copy of Vertical Antenna Comparison by K7LXC and another fellow (N0AX?). It shows actual FS comparisons of magical amateur antennas.

==========
Buck,

For the same reduction in height a top hat has greater efficiency than
a loading coil. It can amount to 3 or more decibels.

But a top hat gets in the way and is more unsightly than a coil.

Have you seen program TOPHAT available from website below.

Of course, that's blatantly false, taken literally. A 2" diameter 10" long solenoid coil coaxially inside a 2.5" ID grounded conductive tube will not have the same phase shift as the identical coil inside a 5" ID grounded conductive tube, and neither will behave the same as the same coil included as a loading coil in Cecil's mobile antenna. It won't even have the same inductance in each case.

Before you say, "Give us a break, Tom. Of course it won't and clearly that's not what was meant," just consider how literally both the posters and the lurkers here take things.

AND in fact, as shown in the simulation I just reported on, the coupling between that coil and the magnetic fields of other nearby components does affect the performance of that coil. In general, when the fields, electric and magnetic, around any component interact with their environment, a change in that environment will change the behaviour of the component. Thankfully, we have a lot of components where that effect is minimal at the frequencies of interest, but we do need to take note of cases where the effect is important. I DAILY work with tiny components that DO behave differently, depending on their environment. At several GHz, seemingly small couplings can be very important.

Cheers,
Tom

I look forward to your tests with turn-to-turn capacitance added to
the model as well. It will no longer match the 100 ohm source and
load over as wide a frequency range, but it will look closer to the
real thing above the self resonant frequency. You may be able to
measure the phase shift versus frequency up to resonance, and test
Cecil's idea that you can measure the self resonant frequency and use
that to predict the phase shift at much lower frequencies.

Mahesh,

Unless you're trying to do a wideband match to a complex impedance, in this frequency range (2-29 MHZ), you really don't need a Smith Chart nor do you need Matlab. . All you need is a pencil & paper and a few very simple formulas.

If you can describe the impedances you're trying to match, the frequency range that the match has to work over, and the acceptable circuit losses, then it would be easier to point you to the best resource for the information you need.

Is "height" in "effective height" really referring to effective radiating length, rather than something to do with elevation above ground (assuming that one is talking about a monopole above a ground plane)?

In other words, is the "effective height" of a horizontal dipole actually related to its end to end length, not its distance above ground?

I am just trying to get started on the right foot in my reading.

So much has been said in this debate - and this is at least the third or fourth re-make of the whole show - that I honestly cannot remember if the exact words that Richard reports were ever used.

If they were, then they were excessively condensed, skipping some essential steps in the explanation. Both sides of the debate have often been guilty of skipping details that seemed "obvious" (at least to their way of thinking) in order to get to their main point.

So please let me try to respond to Richard's criticism above. Since I don't want to skip anything this time, this is going to take a little longer.

If there's anything that someone doesn't agree with, please comment... but please read the whole thing first. Many of the problems with this debate are because people start to throw in comments before finding out where the original poster is heading. This destroys any kind of connected thinking, and reduces the "debate" into a series of disconnected nit-picks.

The main electrical property of the thing we call a "coil" or "inductor" is - obviously - inductance. But a real-life coil has many other properties as well, and these complicate the picture.

If we're going to understand loading coils at all, we first need to strip away all the complications, and understand what loading by pure inductance would do. Then we can put back the complications and see what difference they make.

If we want to understand real-life loading coils, it's absolutely vital to understand which parts of the coil's behaviour are due to its inductance, and which parts are due to other things.

Please have patience about this. If we cannot even agree what pure inductance does, then this debate will run forever...

From the beginning, then:

"Lumped" inductance is another name for the pure electrical property of inductance, applied at a single point in a circuit. It has none of the complications of a real-life coil: no physical size, no distributed self-capacitance, and no external electric or magnetic fields. Its only connections with the antenna are through its two terminals. Lumped inductance is just inductance and nothing else.

Unlike capacitance, inductance has NO ability to store charge. If you push an electron into one terminal of a pure inductance, one electron must instantaneously pop out from the other terminal. If there was any delay in this process, it would mean that charge is being stored somewhere... and then we'd no longer be talking about pure inductance [1].

The inability to store charge means there can be no difference between the instantaneous currents at the two terminals of a lumped/pure inductance. Any difference in amplitude or phase at a given instant would mean that charge is being stored or borrowed from some other time in the RF cycle... which inductance cannot do. There is some kind of difference in phase and amplitude in the voltage between its two terminals, but not in the current.

Therefore any difference in currents between the two ends of a real-life coil are NOT due to its inductance. They come from those OTHER properties that make a real-life coil more complicated.

But let's stay with loading by pure lumped inductance for a little longer, and look at a centre-loaded whip. The loading inductance is responsible for almost all the features of the voltage and current profiles along the antenna.

Starting at the bottom (the feedpoint), voltages are low and currents are high, so the feedpoint impedance is low. Going up the lower part of the whip, the magnitudes of the voltage and current remain almost constant until we meet the loading inductance.

As we have seen, if the whip is loaded by pure inductance only, there is no change in current between the two terminals of the inductance - but there's a big step increase in voltage. At the upper terminal, the current is the same but the voltage is very high, so we're into a much higher-impedance environment.

As we go further up towards the top of the whip, current magnitude has to taper off to zero at the very top. This also means that the voltage magnitude has to increase even more as we approach the top of the whip.

Single-point loading by pure inductance has thus created almost all the major features that we see in a practical centre-loaded whip - particularly the big step change in voltage across the loading coil.

What we don't see in a practical antenna are exactly equal current magnitudes and zero phase shift between the terminals of a real-life loading coil - but that is ONLY because a real-life coil is not a pure inductance. The harder we try to reach that ideal (by winding the coil on a high-permeability toroidal core which confines the external fields and allows the whole thing to become very small), the closer the currents at the bottom of the coil come to being equal. Solid theory and accurate measurements come together to support each other. The only gap between theory and practice is due to our inability to construct a pure inductance that has no other complicating properties.

If we can agree about pure inductive loading, we all have a firm place to stand. Then we can then put back those "other" complicating properties of a real-life loading coil, and see what difference they make.

[1] This principle of "conservation of charge" is also the underlying principle of Kirchhoff's current law. If you connect three ordinary wires together, the current flowing into the junction from one wire must be exactly and instantaneously balanced by the currents flowing in or out on the other two wires. If this was not so, there would have to be some means of adding, storing or losing electrons at the junction... which contradicts our initial assumption of three simple wires with no special properties.

It is not strictly accurate to say that Kirchhoff's current law applies to pure inductance, but the underlying principle of "conservation of charge" does apply.

My *old* physics book doesn't give the proof, but Hecht's Optics does.
Whoops. It's in Waves by Crawford. No mention though that is the proof of
this particular fact. Hecht mentions the experiment, and it may be proven in
subsequent sections using Fourier methods. Waves does it the old fashioned
way. Accepting your comment then, I can read through it with a little more
attention. Thanks.

I am trying to soak up the information on this page.

In the graph of field impedance versus distance (about half way down the page, is this showing the ratio of E field to H field intensities I would measure with very small electric and magnetic pickups placed at these distances?

It looks like this is showing that a mag loop creates a larger E field at some distances than a dipole that is creating the same far field energy propagation. This is quite counter intuitive, so I want to make sure I have not got it wrong.

Never mind. I found something you wrote in an earlier thread:

"There's a common term for the relationship between
the field strength and the length of a conductor,
called the "effective height" or "effective length".
The voltage at the center of a dipole in a field of
E volts/m is simply E * the effective length.
The concept is valid for any length conductor,
not just short ones. The effective length of a
uniform-current dipole is equal to the wire length.
The effective length of a short conventional dipole is
0.5 times the wire length. The effective length
for receiving is the same as the effective length for
transmitting -- in transmitting, it relates the strength
of the field produced to the *voltage* -- not power --
applied across the feedpoint.

If you apply 0.5 volts to a standard dipole
and 1.0 volts to a uniform-current dipole,
the power applied to each will be the same
because of the 1:4 ratio of radiation resistance,
and the generated fields will be the same.
This is consistent with the antenna gains being the same."

This cleared up a lot of the terminology and concepts for me.

3525. adapter help needed

Need some help from guys who've been around this kind of stuff for awhile. I have a coax chassis fitting which takes a UG-536B/U plug. I need to get some kind of adapter to go from UG-536B/U to BNC. Would appreciate identification of what such a fitting would be called, and some sources where I can get one.

If worst come to worst and there isn't any such animal, I may just change out the chassis fitting to a std coax/PL-259 thing.

"Effective length" refers to dipole type antennas in free space.
"Effective height" is the equivalent property of a grounded monopole.
They're often used somewhat interchangeably.

After listening to many voices wiser than me, here's how I plan to set up antenna and 2nd floor shack:

Dipole to twin lead to balun to lightning arrestor to coax to transceiver.

both the balun and lightning arrestor will be close to earth and will be earth grounded at that point.

This earth ground will be connected to copper pipes in the basement and will directly connect to the mains ground.

In the shack, I will use the mains ground only.

Between use, I will disconnect and short the antenna.

Does this sound safe and less likely to induce RF in shack?

Thanks for advice!

John

3529. A Small Indoor FM Antenna

I have a product called RadioShark that is like Tivo for radio. I'm in an area where FM is a bit hard to get. I would like to receive at least one station at 88.7 clearly. There are several in the 88 to 89 range that would do as well. It would be good to have an antenna that does it. I definitely recall a simple dipole that looks like a T that is made from some TV lead wire. That's been hooked to an FM rcvr not far from me, but has never worked to well. Possibly because I have to mount it on a nearby wall and under a shelf. It seems to me that years ago that a rabbit ears TV antenna included FM. Certainly the length of the ears were about right. They seem harder to come by. Something like a desktop model would be good, since RS is hooked into my computer in the den. Any suggestions?

Take 66 inches of twinlead. Bare the ends back about 1.5 inches on each
end and short them. Cut into one side only in the center and bare the
cut wire. Connect it to the 300 ohm input of your tuner with more 300
ohm line, or insert a balun and connect with RG6 coax.

Placement may be as important as antenna design.

I have built several 6, 2, and 543 yagis using 3/16" diameter aluminum rod
(6061) and bought it off Ebay from:

http://cgi.ebay.com/3-16-ROUND-ALUMINUM-ROUND-BAR-ROD-X-40-6061-T6_W0QQitemZ7564034786QQcategoryZ61599QQssPageNameZWDVWQQrdZ1QQcmdZViewItem

The stuff works great and I "Weld" the elements in using Aluminum "welding"
rod, also found on Ebay. Just be sure to follow instructions about cleaning
the metal prior to trying to "weld" it. I use a Mapp gas torch but propane
will work, it just takes a little longer to heat up the metal.

These are the YagiCad dimensions of a 2 element RDF antenna for 166mhz:

ref 00.00m space .906m length
drv 0.069m space .657m length

This uses .010m diameter aluminum tubing. It is being used on a King radio, which I believe is around 50 ohms. I am using 6 feet of rg58/u with a bnc connector.

YagiCad says the f/b is 37.75db and 5.75db gain. Both the H and E patterns are about what I would like in this RDF. It works pretty well when I use it with the elements vertcal, but less well when they are horizontal. I contructed this as accurately as I could.

I don't even know if this antenna SHOULD work, but am wondering if a hairpin would improve what I have so far? Can someone suggest the dimensions of a hairpin for this?

also, this is maybe a bumb question, but is the element spacing designated in YagiCad designs center to center or true spacing between elements? Is there a big diference?

Jim

John, there is always RF in the SHACK!! You are radiating RF from your antenna and possibly feedline. Your shack is quite possibly in the NEAR Field of that antenna. As that RF field propagates outwards from your antenna it induces currents in ALL metal objects, including house wiring, house copper plumbing, etc.

The issue is keeping RF out of the electronics; restated, controlling RF susceptibility.

>> wave. There isn't.
>
> Do you really think that func(kx)*func(wt) is the same thing as
> func(kx +/- wt)? If so, time to dust off the old math books.

(I restored some context)

func(kx)*func(wt) describes the instantaneous current if you pick a
point along dimension, x, and a moment in time, t. It is a map of the
pattern of current over these two dimensions.

func(kx +/- wt) describes a different pattern of the instantaneous
current if you pick a point along dimension, x, and a moment in time, t.

If you put a tiny current transformer around some point of the
conductors in question, (pick an x) and watch the pattern of current
through time (without comparing the phase to any reference) you will
see a sinusoidal current variation for both the standing and traveling
wave cases. The amplitude will vary in a different way, over x, for
the traveling and standing wave cases. If you include comparing the
phase of sinusoidal current cycle you see, to a reference phase, that
will also vary in a different way over x, for the traveling and
standing wave cases.

But regardless, at a point (any particular x) the pattern of current variation as time passes, will be a sinusoid, in either case. There is no difference in kind of current you would measure.

The pattern of how this sinusoidal current varies in both phase and magnitude is very different in the two cases (standing and traveling waves), but you need both a phase reference and multiple locations to see the differences.

The the definition of the word "current", in simplest form, is, the rate of charge movement past a point at some moment in time.

An extension of this instantaneous and point definition might include a sinusoidal cyclic variation through time, by adding a frequency, phase and amplitude, to specify a common pattern of current over time, but still at a point.

Adding in an additional function of position allows the extension of this definition of current over time to also include spacial variation of the time dependent pattern.

But if you say the words "the current is different", and don't include a lot of additional verbiage to indicate that you are talking about the two dimensional pattern of the variation of current over time and location, some people are going to misunderstand you and argue based on picturing another definition of what might be legitimately meant by the word, "current". I made it clear what definition I was using for the word "current" (the instantaneous point definition) and you are arguing with me, while using some different definition.

I realize that I am being pedantic, here, and stating the painfully obvious. But if your goal is to have other minds synchronize with the abstract thoughts rippling through your mind, you have to be pedantic.

If you are just using this topic to argue, because you enjoy argument,

then never mind.

Several years ago some friends and I did a somewhat crude analysis of the radiation pattern from a mobile on 11 meters. We found that as we took reading from around the car that the field strength varied as much as 10db from the highest to lowest reading. From this we not so seriously concluded that its not so much the antenna but the car that makes a difference in how well you are going to get out.

John P. wrote, among other things,

"The pattern of how this sinusoidal current varies in both phase and magnitude is very different in the two cases (standing and traveling waves), but you need both a phase reference and multiple locations to see the differences. "

Do you really need the phase reference? Traditionally (since the beginning of measuring them, and sometimes still today), standing waves on a uniform transmission line have been measured by finding a point of minimum amplitude (as measured by voltage, or alternatively by current) and a point of maximum amplitude, with no reference to phase. In fact, SWR was reasonably defined as the ratio of max/min amplitudes. If you know that the wave you're observing is a sinusoid and you have min and max amplitudes along the line, then you can resolve the wave into two travelling-wave amplitudes; you won't know which is which but you will know the two amplitudes. If there is but one source in the system, it's reasonable to think that the higher amplitude travelling wave was the one coming from the direction of that source.

In fact, you don't even need to find the minimum and the maximum points. Again, given sinusoidal excitation and a uniform line, some small set of points with accurate amplitude measurement at each will suffice, since they will uniquely determine the amplitudes of the two waves and the line attenuation. You would have to know the spacing of the points and that they were dense enough that there is not a spacial aliasing problem (points distributed over more than 1/4 wavelength...).

It's common to think of a standing wave as the result of two travelling waves, one in each direction, but another way to think of a standing wave pattern is as a pure standing wave plus a pure travelling wave. The minimum-amplitude represents the amplitude of the travelling-wave portion. The difference between max and min represents the amplitude of the standing wave portion. For some folk, it's enlightening to see an animation of the waves for several different values of SWR.

Cheers,
Tom

> saying.

I'm back from Tulsa and had time to think while I was gone.
Given that none of the measurements reported so far actually
measured the phase shift through a coil, I have devised an
EZNEC example that should be very easy to duplicate for
real world measurements.

Previously I had offered a 5.89 MHz base-loaded antenna as
an example. The top of my antenna was the typical open-
circuit with its 100% reflection at the tip. W7EL took my
file and connected the top of the coil back to ground. He
changed the 'tip' of the antenna to a short-circuit to
ground so the 100% reflection at the 'tip' remained. All
that shorting the top of the coil to ground accomplished
was different phase shifts in the reflected wave. Any
information contained in the standing wave current phase
continued to be zero because of unchanging phase.

So here's the EZNEC example and an experiment that any
properly equipped person can duplicate. That includes
you and W7EL.

I took W7EL's EZNEC file and changed wire #203 from 0.25'
to 31.25'. At the 'tip' of the antenna, I installed a
439.2 ohm load that turns the antenna into a 90 degree
long *traveling-wave* antenna. Note that the current
magnitude at the top of the coil is identical to the
current magnitude through the load resistor. The load
resistor's value is very close to the calculated Z0
of the 31' #16 wire two feet above ground, using the
formula for a single wire transmission line above
ground.

The graphic is at http://www.qsl.net/w5dxp/test316y.GIF

The EZNEC file can be downloaded from:

http://www qsl.net/w5dxp/test316y.EZ

I will add the supporting text to my web page later today.

Please explain the 15.68 degree phase shift through the
coil. Don't you find it strange that all the wire in the
system occupies 90.01 - 15.68 = 74.33 degrees?

(snip)

What I was trying to say is that to completely see (measure) all the
differences between the current pattern in a standing wave versus a
traveling wave (or any combination of traveling waves of different
magnitudes in opposite directions, with or without losses, especially
when there are discontinuities in the conductor, like loading coils)
those observations would include phase versus position.

In many practical cases, you can infer what you need to know about the
two traveling waves by just taking amplitude measurements, as you suggest.

Which points out, once again, that the phase information in a
standing wave is contained in the amplitude, not in the phase.
W7EL measured the *phase* of the standing-wave current which
is known not to contain any information as it is close to
unchanging all along a 1/2WL dipole or 1/4WL monopole. Yet he
reported it as meaningful. So far, nobody has made meaningful
phase shift measurements through a loading coil.

> It's common to think of a standing wave as the result of two travelling

One cannot get away from the fact that the pure standing wave
is the superposition of equal amplitude traveling waves flowing
in opposite directions. Some part of the forward traveling wave
must be allocated to the standing wave function. That part of
the traveling wave transfers no energy.

|Ifor| - |Iref| = |Ifor'| the part of the forward traveling wave
that is transferring energy.

|Ifor| - |Ifor'| = |Ifor''| = |Iref| the part of the forward
traveling wave that is contributing to the pure standing wave
and transferring no energy.

Excellent!

Can you use this example, with varying frequency to explore your
assertion that the time delay (frequency times phase shift) of the
coil varies little over a significant range of frequencies up to self
resonance, and that that delay is about 1/4 cycle of the self resonant
frequency?

A graph of delay versus frequency would be useful. It should show
over what frequency range the coil acts mostly like a transmission
line and where it acts mostly like something else (i.e. inductor,
parallel resonant tank).

This coil, operated below its self-resonant frequency, has
phase shift of 15.68 degrees or ~0.044 wavelength (delay of
7.4 nS). Dr. Corum says anything over 15 degrees requires
the distributed network model. 15 degrees will transform
50 ohms to 54+j120 ohms, causing SWR to be erroneously
reported as 7:1 instead of 1:1. That sounds like too
large an error to me.

Since the lumped-circuit model assumes a delay of zero, i.e.
faster than light, seems the use of the lumped-circuit model
results in 100% error, or infinite error if one calculates
it the other way. :-)

BTW, one of the principles on the other side of the argument
sent me a file with a worm in it. I guess he wanted to
extend the silence caused by my trip by bringing down my
computer.

Not if the lumped inductor model includes lumps of capacitance that
represent the strays to ground. Lumped LC networks exhibit phase
shift, also.

Strange?

1. The current distribution shown on the web is different than
the current distribution shown in the model;
2. -4.91 + -20.59 + -90.01 = -115.51 is different than
90.01 - 15.68 = 74.33
3. The coil Vf shown on the web is 0.1375 is different than
eq (32) => 0.0078
4. refuting your own references (Corumï¿½).

not strange at all.

Please don't put words in my mouth. What I have previously said
is that the delay can be *ROUGHLY* calculated using the self-
resonant frequency. I said something about +/- 50% accuracy.
Here's what EZNEC reports as the phase shift through the coil
in the traveling wave antenna previously tested at 5.89 MHz.

5.5 MHz: 14.1 deg, 5.89 MHz: 15.7 deg, 6 MHz: 16.2 deg,
7 MHz: 21.4 deg, 8 MHz: 29.5 deg, 9 MHz: 45.9 deg,
10 MHz: 89 deg, 11 MHz: 141.4 deg, 12 MHz: 163.0 deg,
13 MHz: 172.3 deg, 13.7 MHz: 183.82 deg.

The linear delay calculation is off by 59%, not too far from
my 50% rough estimate. Please note that the above values of
delays reported by EZNEC are nowhere near the 3 nS measured
by W8JI in the standing wave environment.

wrote:
>delay of 7.4 nS

Hmm, giving Tom the same grace of 59% reveals that the figures above,
7.4nS ï¿½59% (4.4 - 11.77)
and
3nS ï¿½59% (1.77 - 4.77)
overlap.

The thing about error (especially when it is in a growth mode
indicating loss of control over the experiment) is that you don't know
where within the band of possible values that the actual value
resides.

So, comparing the one to the other, making a claim that the other is
invalid, must necessarily invalidate both as they are convergent. Such
is the legacy of poor quality control.

It might be tempting to perform a Hail Mary save, by suddenly
declaring they are both right. :-)
but at 59% error, we can all agree that's a fantasy. Stretching your
tolerance for error to fit your argument can lead to any conclusion.

> 2. -4.91 + -20.59 + -90.01 = -115.51 is different than
> 90.01 - 15.68 = 74.33

The phase of the source is referenced at zero degrees. The
currents along the antenna are lagging the source current.
-4.91 deg is the phase of the current at the bottom of the
coil. -20.59 deg is the phase of the current at the top of
the coil. -90.01 deg is the phase of the current at the end
of the antenna. Trying to add those phases shows a lot of
ignorance.

> 3. The coil Vf shown on the web is 0.1375 is different than
> eq (32) => 0.0078

Sorry, you're wrong. eq(32) for this coil yields a VF of ~0.033
which Dr. Corum claims to be accurate within about 10%. The
coil VF on the web is at 5.89 MHz, *NOT* at the self-resonant
frequency.

> 4. refuting your own references (Corumï¿½).

Dr. Corum's equation for the coil VF is at its *SELF-RESONANT*
frequency, not anywhere else. Using it anywhere else is only
a *VERY ROUGH* estimate. At the self resonant frequency reported
by EZNEC, the VF calculates out to be ~0.055.

Hi Richard,
Cecil never actually reads his references, he just
gives them and hopes you won't read them either. If he'd
bothered to look at figure 2 in the Corum reference he would
have found that the Corums had in mind a shorted stub as a
substitute for their Tesla coil. That's o.k., since it would lead
to an inductance (jZc*tan(Betag*h)) which they could use in the
time-honored way to resonate with the capacitance of the rest
of the circuit.
You're right, not strange at all.

Now, that is certainly a lie. :-) Remember, W8JI said that
any answer is better than no answer. That presumably includes
his wrong answers. :-)

> Stretching your
> tolerance for error to fit your argument can lead to any conclusion.

It's not a tolerance for error. It's a recognition that the
answer is, so far, unknown. I've said it before: The delay
through the coil is what it is and we don't know exactly what
it is. That it is difficult to estimate or measure has absolutely
no effect on its value in reality.

What we know for sure is that the presuppositions of the
lumped-circuit model indeed do violate the laws of physics.
Faster than light propagation through a coil comes to mind.

I am admittedly surprised to see the velocity factor fall
so rapidly with frequency. My surprise has absolutely no
effect on reality. I just use the scientific method to
adjust my concepts and move on. However, to paraphrase an old
TV commercial, "It's not nice to fool Father Guru". The earth
may reduce to a quantum singularity when the r.r.a.a gurus
recognize their errors. :-)

But please remember the original assertions by the gurus. There
is ZERO phase shift through an inductor. There is ZERO amplitude
change through an inductor. This can easily be proven by observing
the lumped inductances in EZNEC. W7EL shot down those arguments
by installing the helix feature in EZNEC. :-)

pardon me, but have you looked at the periodic table lately?

Hydrogen is made up of a single proton and a single electron. it tends to leak through just about any material regardless of thickness. helium, OTOH, is a construct of a proton, a neutron and a single electron (may have more than one depending on isotope, etc) and will tend not to leak nearly as much.

Hydrogen is far more plentiful in the environment, but happens to be quite flammable (read that as EXPLOSIVE!). Helium is not flammable and much safer, though a bit harder to come by (hence its cost).

3564. Spam and worms

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-26 20:10:08 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <122dt93a1b06e01@corp.supernews.com>
Source record: 62225

I've now gotten two emails from other newsgroup participants about messages containing a worm or virus with my email address in the "From" line. One was well-meaning, the other accusatory.

When a worm or virus infects a computer, it commonly sends itself to addresses in the victim's address book. It forges other addresses from the address book into the "From" and "Reply-to" lines. One thing you can *always* count on is that a spam, worm, or virus email *never* comes from the location in the "From" or "Reply-to" lines of the header. If you've gotten one which has my address in one or both those lines, it means simply that both our addresses are in the victim's address book.

Senders of spam also *always* forge return addresses, and sometimes use a genuine address they've gathered at random, or occasionally use one purposefully as a means to harass someone. Some time ago, a major spammer decided to use mine for a while, and I got about 100 bounce messages per day for a couple of months as a result.

If you want to help stop the spread of the worm, go to http://www.spamcop.net/anonsignup.shtml. Click the link labeled "Learn more about what to report and what not to report to SpamCop" and read the section about viruses. Then sign up to use their automated spam tool. It's able to parse through a forged header and detect the true origin of an email message. Follow the directions for "Viruses" at http://www.spamcop.net/fom-serve/cache/125.html. This will notify the ISP that one of their customers' machines is infected, and enable them to identify which machine it is.

Because my email address appears in a lot of address books, I see infections from time to time in the form of bounce messages resulting from the worm being sent to invalid addresses. There was a particularly bad one a while back on some German ham's machine which got me a lot of bounce mail. This one is apparently in the machine of someone who reads this newsgroup or at least has occasion to email some of the participants.

Reg is correct. Even a very short structure, much shorter than a wavelength, acts like a transmission line. A short structure just acts like a short transmission line. It's just that if it's short, there are simpler ways to analyze it which will get us essentially the same answer. But we can use full blown transmission line analysis on any structure if we choose, and should get the correct answer.

I just bought Mathcad and am trying to learn to use it.
The graph of the above data is really interesting. Somewhat
like a sine function, this curve has an inflection point
around 10 MHz where the phase shift is changing most rapidly.
On either side of 10 MHz, it doesn't change as rapidly.
10 MHz appears to be the 1/8 wavelength point where
|Z0| = |XL|.

> structure if we choose, and should get the correct answer.

Seems that you agree that the distributed network model works for
all common problems. That makes sense since the distributed network
model is a superset of the lumped-circuit model.

Using Dr. Corum's rule that models should be switched at 15 degrees,
15 degrees of a 450 ohm transmission line will transform 50+j0 ohms
to 54+j120 ohms. The difference in 50 ohm SWR is 7:1 Vs 1:1. That
seems like a pretty large error to me just to be able to stick
with the lumped-circuit model.

C'mon Reg! We both know that a 1/4 inch diameter loop is NOT a
transmission line at 0.1 MHz. :-0

Tom Donaly wrote:
> What about figure 2, Cecil?

Figure 2 suggests that any coil with a delay over 15 degrees
should be analyzed by discarding the lumped circuit model
and instead using the distributed network model. Every coil
I have talked about on this thread has a delay greater than
15 degrees. 15 degrees of impedance transformation will transform
50 ohms into 54+j120 ohms with a difference in SWRs of 7 to one.
Does that really sound like a reasonable reason for keeping the
lumped-circuit model?

Roy just said in another posting that the reflection model
will solve all the problems that the lumped circuit model
will solve. It just gets clumsy as far as the math goes.

It is interesting to watch the gurus retreat into fantasy
where they were only ever talking about tiny point inductances
to start with. Anyone who has been following this argument
over the years knows otherwise.

Figure 2 shows that the authors considered their model to be
that of a shorted stub to replace the inductance of their Tesla
coil. They didn't say that a coil of wire is a shorted stub,
only that it performs the same function as one in the calculations.
You're waffling and trying to slick your way out of an embarrassing
situation again, Cecil. O.k., I'll accept the shorted stub
substitution. Heck, I'll even accept a solution involving
op-amps, (provided you don't use it in transmit mode). What I won't
accept is pretending a long hank of transmission line with a load
at one end performs the same impedance transformation in the same way
as a coil of wire.

If we do, we're going to have our work cut out for us. When the
fundamental quantities L, R, C, and G are unknown functions instead
of constants, analysis gets tricky. If it didn't get tricky, we could
solve for currents on conductors with simple equations instead of
having to use moment methods to numerically solve intractible
integral equations.

The key word is *diatomic* -- in this context it refers to the fact
that in its gaseous form, hydrogen is present in the moecular form
comprising two hydrogen atoms. This property is also shared by
nitrogen and oxygen.

This H2 molecule is larger than the solitary He -- that's why He is
used in leak detectors.

It's my problem that you don't know how to turn on the
'Current Phase' option in EZNEC??? Just how do you propose
that I gain control over your computer? It states on the
graphic that the 'Current Phase' option is 'ON'.

>>Trying to add those phases shows a lot of ignorance.
>
> Ah! Leading with your chin again.

If you are really into adding up phase angles, then add
them up every inch. You will approach infinity as the sum.
Your approach is a lot like adding up power every inch
and declaring the transmission lines contains eighteen
gigawatts of power.

It appears that Cecil is back with many postings, but he seems to be ignoring answering my question. Perhaps he's unable to do so. Just so the lurkers understand that indeed it is possible to work through the phasor math, here goes. Here's exactly the scenario Cecil set up, quoted from his posting:

==========

"So to be perfectly clear, here is my statement re-worded using a 45 degree phase shift through the coil.

The forward current magnitude is equal at both ends of the coil.
The reflected current magnitude is equal at both ends of the coil.

At the bottom of the coil, the forward current is 1 amp at zero deg.
At the bottom of the coil, the reflected current is 1 amp at zero deg.
At the bottom of the coil, the standing wave current is 2 amps at zero deg.

At the top of the coil, the forward current is 1 amp at -45 deg.
At the top of the coil, the reflected current is 1 amp at +45 deg.
At the bottom of the coil, the standing wave current is 1.4 amp at zero deg."

==========

OK, so the difference in "FORWARD" current from the bottom to the top is:
fwd.bottom.current - fwd.top.current
= 1A at 0 degrees - 1 amp at -45 degrees
= 1+j0 - sqrt(.5)-j*sqrt(.5)
= 1-sqrt(.5) + j*sqrt(.5)
(about 0.765 at 67.5 degrees)

The difference in "REFLECTED" current from the bottom to the top is:
refl.bottom.current - refl.top.current
= 1A at 0 degrees - 1 amp at +45 degrees
= 1+j0 - sqrt(.5)-j*sqrt(.5)
= 1-sqrt(.5) - j*sqrt(.5)

The SUM of these two differences is:
[1-sqrt(.5) + j*sqrt(.5)] + [1-sqrt(.5) - j*sqrt(.5)]
= 2 - 2*sqrt(.5) + j0
= 2 - sqrt(2) + j0
= 2 - sqrt(2) at zero degrees

The standing wave current at the bottom of the coil is 2 amps just as Cecil suggests at one point: It's the sum of the "forward" and "reflected":
net current at the bottom = sw.bottom.current
= 1+j0 + 1+j0
= 2+j0
= 2 at zero degrees

Presumably Cecil meant that the standing wave current at the TOP (not the BOTTOM) of the coil is 1.4 amps at 0 degrees. That's close, but more exactly, it's
net current at the top = sw.top.current
= sqrt(.5)-j*sqrt(.5) = sqrt(.5)+j*sqrt(.5)
= 2*sqrt(.5)
= sqrt(2)
= sqrt(2) at zero degrees.

So the difference in net current (that is, the difference in the standing wave current) between the top and the bottom of the coil in this example is exactly:

sw.bottom.current - sw.top.current
= 2 at zero degrees - sqrt(2) at zero degrees
= 2 - sqrt(2) at zero degrees

So, we see that the difference in current between the bottom and the top is exactly the same, independent of whether we just use the standing-wave currents, or the currents in the "forward" travelling wave plus the currents in the "reflected" wave. That it's also
exactly the same answer you get by looking at a full cycle of instantaneous currents is left as an exercise (fairly simple) for the reader.

Either way, there is a difference, and that current must go somewhere. It should be pretty easy to account for it. In fact, it's not even very hard to predict fairly accurately in the case of a loading coil in an antenna perpendicular to a ground plane or equivalently in a symmetrical doublet.

Cheers,
Tom

> 5.5 MHz: 14.1 deg, 5.89 MHz: 15.7 deg, 6 MHz: 16.2 deg,
> 7 MHz: 21.4 deg, 8 MHz: 29.5 deg, 9 MHz: 45.9 deg,
> 10 MHz: 89 deg, 11 MHz: 141.4 deg, 12 MHz: 163.0 deg,
> 13 MHz: 172.3 deg, 13.7 MHz: 183.82 deg.

Here is that list repeated in units of time, instead of degrees:

MHz ns delay
5.5 7.1
5.89 7.4
6 7.5
7 8.5
8 10.2
9 14.2
10 24.7
11 35.7
12 37.7
13 36.8
13.7 37.3

I would have to graph this on a log frequency plot to see the
frequency breakpoints, but I think this looks a lot like a short piece
of transmission line below about 6 MHz and like a resonator above
that. I expect the delay to start to fall at higher frequencies as
the turn-to-turn capacitance takes over.

What do you see?

last time I checked Helium has 2 protons and 2 electrons. I think the
previous poster implied that hydrogen exists as molecular hydrogen: H2,
as opposed to He that is mono-atomic.

However, you have the better point: Hydrogen spells danger. Hydrogen,
Hindenburg,...If being a survivor means being a pansy...cool.

> = 1-sqrt(.5) + j*sqrt(.5)
> (about 0.765 at 67.5 degrees)

That is truly magic. Someone must have slept through class that
day.

Good grief! You can't subtract two currents that are a foot apart
from each other. Currents superpose at a point. Currents from
each end of the coil a foot apart don't superpose. They don't
even know each other exist. Good Grief!

```
Ifor=1A at 0 deg Ifor=1A at -45 deg
-----------------X-/////////-Y------------------
Iref=1A at 0 deg Iref=1A at +45 deg
```

The forward current superposes with the reflected current at the
bottom of the coil to get 2 amps at zero degrees. The forward
current superposes with the reflected current at the top of the
coil to get 1.4 amps at zero degrees. The delay through the coil
is 45 degrees.

Neglecting losses:
The energy in the forward wave is the same at the top and bottom
of the coil. The energy in the reflected wave is the same at
the top and bottom of the coil. There is zero net steady-state
energy storage between the top and bottom of the coil. There's
no RF battery there.

I see something that resembles part of a sine wave with
a point of inflection (resembling a zero crossing) around
10 MHz. The phase shift around 10 MHz is 60 degrees per
MHz. The phase shift above and below 10 Mhz is lower.
I sure can see why the lumped circuit model is a total
and complete failure when applied at 10 MHz. I also can
see why Dr. Corum chose 15 degrees as his cutoff point.

You have my sympathies, Roy. I know just what you mean. For six years I was heavily involved with the IARU Intruder Watch and, like you, my address was in a lot of people's address books, with the expected result whenever any of those computers became infected. One particularly embarrassing infection sent an infected message every few days to the U.S. FCC, and of course I would get the FCC's automatic reply saying that an "unacceptable attachment" had been deleted from "my" message to them. This went on for about six months and I was never sure whether it was just due to some idiot who never ran a virus scanner or was actually malicious. I suspect the latter. They say education would solve a lot of these problems but I have often wished there was some silver bullet that could be sent to the offending computers HI.

Good luck and 73,

Sorry you've missed the point, Cecil. I can only hope the lurkers get it.

(Aside: I'm not exactly sure what you mean by "no net steady-state energy storage." If that's true, then there's never ANY current in the inductor, because the energy stored in an inductor's magnetic field is i^2*L/2, and that's always positive for non-zero i.)

Cheers,
Tom

You are leading yourselves astray again.

Anything which produces a velocity factor which varies significantly
with frequency is INCORRECT.

The propagation delay (in nano-seconds) along a coil is a constant and
is independent of frequency.

It depends only on the physical dimensions of the coil, ie., on L and
C, which are fixed in a given situation.

This is just the same as on an ordinary transmission line.

Reg.

A bit more on this...

I trust it's an accurate summary to say that Cecil gave us the "forward" and "reflected" currents at both ends of a coil, and correctly deduced the standing-wave currents at each end from those. But given that information, Cecil is unable (and believes it is impossible) to determine the net charge in the volume containing the coil as a function of time (to within a constant, at least), even though the the wires in which we know the currents are the only way for charge to get in and out of that volume. I do hope we can at least agree that current is the rate at which charge passes a point...

And I do hope most folk tuned in here don't have so much trouble with it.

Farewell, goodbye, auf wiedersehen, adieu...

Tom

THERE IS NO RF BATTERY STORING ENERGY! THERE IS ZERO LONG TERM
ACCUMULATION OF CHARGE! Neglecting losses, energy in exactly equals
energy out over the long term.

The fact that 2 amps of standing wave current exists at the bottom of
the coil and 1.4 amps of standing wave current exists at the top of
the coil doesn't imply any long term accumulation of charge. Long
term accumulation of charge in a coil is impossible.

Thanks, Tom, for taking the trouble to go through the numbers. As I said earlier, most of us know, and all engineers certainly should know, superposition requires that results from an analysis using the total current must be the same as the sum of the results from separate analyses using forward and reflected currents (or any other components whose sum is the total current). Your analysis shows this, as it should.

Roy Lewallen, W7EL

3611. Signal Strength Meter for Mobile Phones

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-27 06:54:22 UTC
From: Mark
Message-ID: <964e2251k12b5qdluiracisc0fnkhdtoiu@4ax.com>
Source record: 62272

I currently offer a service for Mobile Phone users in rural/remote areas, where I fit a Yagi antenna for people with poor reception problems. At the moment I use a Mobile Phone's signal strength reading (along with a map and compass) to locate the strongest signal from the nearest base station (the region where I work, there is only one service provider). Because these readings are a bit slow to respond, I would like to build/buy a simple signal strength meter to be a bit more accurate, when setting up these antenna's. I either need something with a meter or even simpler (and maybe better) headphones listening to the familiar signals sent out by these things, to find the strongest signal. Because I work in very remote areas normally, I am guessing that the base station signals, should not be that hard to distinguish from the normal mish mash of mobile phone signals. Would anybody be kind enough to supply me with a diagram or a web site etc, to help me on my way? PS 950Mhz.

I think everyone here except Cecil knows where the current goes.

If Cecil admits to displacement currents, he has to also admit his
argument about reflected waves is incomplete.

Buck, I have discovered, as you have, that all search engines were not created equal. I'm going to try the new one "ask" (I think thats the name) and see if it works equally as confused as the others.

Roy, would you please explain what is the technical significance
of Tom's superposing the forward wave of 1 amp at zero degrees at
the bottom of the coil with the forward wave of 1 amp at 45 degrees
at the top of the coil when those two currents are separated in
space by 12 inches and separated in time by 45 degrees of a cycle?

Doesn't the superposition principle require the two signals to exist
in the same space-time? The misconceptions being presented here are
unbelievable but apparently exist in the engineering community.

Those are standing wave currents, Tom. What is it about
func(kx)*func(wt) that you don't understand?

Take a look at the standing wave current distribution on a one
wavelength dipole at:

http://www.qsl.net/w5dxp/1WLDIP.GIF

The position in which a coil is installed in the standing wave
environment determines the magnitudes and phases of the currents
at the top and bottom of the coil. No magic displacement current
is required. If magic displacement current is not required in
a transmission line, why is it required in a coil? Hint: because
the lumped-circuit model is flawed.

> If Cecil admits to displacement currents, he has to also admit his
> argument about reflected waves is incomplete.

We can assume zero displacement current without much changing anything.
In the example at the top of this posting, there sure isn't 0.6 amps
of displacement current. I'm beginning to believe that you don't
understand superposition of forward and reflected waves. That would
explain a lot.

In the above example, the forward and reflected currents superpose to
0.7 amps at the top of the coil. That is simply closer to the standing
wave current maximum point. No displacement current required.

The forward and reflected currents superpose to 0.1 amp at the
bottom of the coil. That is simply closer to the standing wave
current minimum point. No displacement current required.

Exactly the same thing happens along a transmission line with reflections. There's negligible displacement current between the 0.1 amp point and the 0.7 amp point on a transmission line. For exactly the same reason, there can be negligible displacement current in the coil. The forward current and reflected current superpose in a coil just as they do in a transmission line.

If you would use the proper model and you will not need to resort to any magic displacement current which is just a patch on a gaping hole in the flawed lumped-circuit model.

> I feel sorry for anyone who has to deal with you on a daily basis.

The distributed network model, with its superposition of forward
and reflected waves, explains everything without having to
resort to displacement currents.

The distributed network model is more powerful than the lumped
circuit model. The lumped circuit model is a subset of the
distributed network model.

When the two models agree, all is well. When the two models
disagree, the distributed network model is right and the
lumped circuit model is wrong.

You assume displacement currents exist because your model
requires them, not because they exist in reality. The distributed
network model illustrates just how unimportant displacement
currents really are. In the distributed network model, displacement
currents are often omitted as negligible.

In a high-Q coil, in a standing wave environment, radiation from
and losses in the coil are often negligible and can be ignored.
The large part of what happens to the standing wave current is
simply superposition of the forward and reflected waves. No
magic explanations required.

The delay through a real world 75m bugcatcher coil, predicted by
the distributed network model, is tens of degrees, not the faster
than light speed predicted by the lumped circuit model.

Cecil,

I believe the long term average current is also zero. Therefore all of
these coils and antennas are totally inert. Problem solved.

It is a mystery why the discussion randomly switches from degrees of
phase and nanoseconds of time delay to long term averages, RMS, and
"net" something or other.

If you don't understand accumulation of charge in *every* AC and RF
circuit then there is little hope that you will ever get to an
understanding of the now-infamous "current through coil" problem.

I understand the movement of charge within a cycle, Gene. But
it is irrelevant to the discussion and just another one of
your strawmen erected as a diversion away from the relevant
issues. Why do you think such a transparent diversion
would work?

During a cycle, energy is obviously exchanged between the
E-fields and H-fields. For a 1/4WL antenna, that means
migration from end to end. But everything being discussed
so far are RMS values. EZNEC reports and displays RMS values
of current. All of the measurements reported so far were
RMS values.

There is no net storage of energy in the coil based on the
product of the RMS voltage and the RMS current. Everything
about RMS standing wave current can be understood simply by
superposing the RMS values of forward and reflected current.

func(kx+wt) + func(kx-wt) = func(kx) * func(wt)

You were the one who posted that information. I don't
think you quite realized what a boost that was for the
distributed network model. The lumped circuit model has
no provisions for accomodating the above equation and
presupposes faster than light propagation.

Your next logical diversion will probably be - trying to track
the position and velocity of an individual electron in an
antenna. :-)

Cecil,

Your response shows you don't understand, or more likely, you are faking
a non-understanding. Charge storage is virtually equivalent to voltage.
Are you suggesting that there is no RMS voltage in these configurations?

And as to your point about my "boost" of the distributed model: I am
neither boosting nor de-boosting any particular model. I don't believe
there is another person participating in this thread who is claiming one
model trumps the other, except you. Each model has its place, but that
place is dictated only by mathematical convenience. It could be really
tedious to set up complex problems with the less convenient model, but
that does not mean it cannot be done.

Gene, everyone knows that an inductor stores energy during part
of a cycle and gives up that same energy, minus losses, during
the other part of the cycle. That knowledge is irrelevant to
the present discussion. Your attempt at a diversion is more than
transparent. Why don't you discuss the real issues?

> I don't believe
> there is another person participating in this thread who is claiming one
> model trumps the other, except you.

I suspect those people know when the lumped circuit model fails.
Your own posting about standing wave current phase proved that
W7EL's phase measurements were meaningless. Here's what you said:

Regarding the func(kx)*func(wt) standing wave current term:

> Gene Fuller, W4SZ wrote:
>> In a standing wave antenna problem, such as the one you describe, there is no
>> remaining phase information. Any specific phase characteristics of the traveling
>> waves died out when the startup transients died out.

>> The only "phase" remaining is the cos (kz) term, which is really an amplitude
>> description, not a phase. The so-called "phase reversal" in longer antennas is
>> not really about phase either. It is merely a representation of the periodic
>> sign reversal seen in a cosine function.

That is technical fact. Thanks for stating it.

It is not the size of the atom that is relevant here. The important
thing is the size of the molecule. Helium is a one atom molecule while
Hydrogen is a two atom molecule. A single atom is much smaller than a
two atom molecule. Hence helium being the only single atom molecule in
existence, it is the king of jail break being able to slip through the
bars of any plastic prision cell.

Technical facts *are* a deeply personal issue with me. So I ask
you the same question here: When are you going to correct the
technical errors on your web page? The delay through a 75m
mobile bugcatcher coil is tens of degrees, not faster than the
speed of light. Your chosen model has you hoodwinked into
assuming the proof. Its presuppositions cannot be used as proof
of anything which is all the proof you have ever presented.

Please note that nobody has made valid measurements of the delay
through a loading coil. The closest thing to a valid measurement
presented thus far is the EZNEC simulation on my web page at:

http://www.qsl.net/w5dxp/current.htm

which I updated just this morning. I'm hoping some objective person
will make the traveling wave measurements and report them here. And
I'm willing to predict it won't be the people defending the lumped
circuit model for fear of what they will measure.

> No matter what happens here, Cecil will run off someplace else and
> report everyone supports him and give some personal argument why. I
> suspect that is becuase he really hasn't a leg to stand on technically
> and he knows it.

Neither you, not anyone else, has been able to poke a hole in the
distributed network/reflection model. Wonder why that is? When
there is a disagreement between the distributed network model
and the lumped circuit model, the distributed network model
wins every time because that is prima facie evidence that the lumped
circuit model has ceased to function under the given conditions.

Why are your postings so lacking in technical content?

Most precisely it is a form of half waves in phase. Putting half wave radiators in a line like that (also called co-linear because they are on a common "co" line "linear") gives gain by compressing the radiation into the volume (a disk or flying saucer- like shape) perpendicular to the "line" of the elements.

It is a common type used in cellular base stations. Each section is approximately a half wave long. It is approximate because of the velocity factor of the coax and other factors. Reversing the center and shield for each section is the way the sections are all brought into the same phase.

I believe the ideal spacing (for gain) of half waves in phase is 1/2 wavelength. However the "reversed coax" construction is easier. It does not need some type coaxial phasing lines to feed all the separated elements and do it in phase.

The use of the term "sector" (by the author of the web site referenced) for each of the coax sections may be a misuse of the term "sector" which comes from the antennas common use in the cellular field with an added corner reflector that makes it have a 120 or 60 degree-wide pattern and thus used to cover only one Sector of a sectorized cellular site. Wi-Fi base stations can also have 3 or 6 sectors and use this type of sector antennas (with the reflector).

Hope this helps understand.

Dear Antagonists,

Why go to the great hazardous trouble of measuring it when it can
easily be calculated from physical dimensions of the coil.

Velocity V = 1 / Sqrt(L * C) metres per second

where L and C are henrys and farads per metre.

Therefore Seconds Delay = Coil Length in metres / Velocity.

OK, I admit it's an approximation because coil turns couple one part
of the 'line' to another a short distance away. It is not unconnected
with proximity effect. This does not occur in a normal transmission
line. But the approximation holds.

See and amuse yourselves with program TRANCOIL.

Yes, I think I will have to drill a hole somewhere and mount the antenna (Yagi) outside the house. I made a 300 ohm lead antenna and mounted it on a 5' long board, so that I could move it around. It really didn't have any impact. I had hoped being close to a window would help, but nay. So that I don't have to mount the antenna on my roof, it seems possible to mount it some 50' from the house and transmit the signal to the house. I think I've seen some device like that for office use. They put it in a window, and distribute the signal inside the office to people who have FM (maybe AM too) radios. Maybe RShack or SuperCircuits sells them. Don't recall where I've seen them.

****
He also says it has "two sectors" when it actually is three half waves in
phase. His "whip" is one half wave.

I also forgot that due to the coax loss factor, the gain is not the ideal,
for close half waves in phase, either. It IS very easy to make, however.

I also wonder if he has the dimensions incorrect with the, as he calls it, "whip" shorter than the coax sections. I haven't designed these, but it seems the "whip" should be a free space half wave long and the coax sections a "coax" half wave long.

Another consideration is the fact that these are not full half wave *radiators*, but shortened approx to 66%, or 0.33 lambda (when using this coax). I don't know how much effect the shorter element (vs. having full half wave elements at this tip-to-tip spacing) affects the gain compared to precisely getting 180 degrees of phase shift (or getting non-180degrees to get closer to half wave radiators) , not to mention the feed impedance. I believe commercial antennas like this use air line to get closer to true half wave radiating elements.

Hope this helps understand.

Let me rephrase. Everything about RMS standing wave
current can be understood simply by superposing the
values of the forward and reflected current phasors
whose phasor length is (usually) represented by their
RMS values.

The phasor arrow length is customarily the RMS value
of the phasor so the superposition of phasors turns out
to result in an RMS value. That's what I meant.

When EZNEC says the source current is 1.0 amp at zero
degrees, that is an RMS value. If the source voltage
is 50 volts at zero degrees, multiplying voltage by
current will yield the power input, i.e. 50 watts.

Wayne,

I don't know if the others answered your question, but be careful. Your original post says:
"...two antennas separated by a distance D would have a resolution as the same as an antenna of size D,..."

Resolution is key here, not, as you state later,: "..can act as though they are a single receiver of size D"

"Resolution" vs. "act" may be ambiguous.

I'll take a stab.

Think of water waves. Picture some very nice, regular waves. All the same size, shape and wavelength. This is a good analogy for RF.
Now, put two *vertical* antennas in the pool (come-on in the water's fine). From the top they just look like dots right?

First, position them so they are in the same line with the wave front -- so each wave hits both at precisely the same time. (a broad-side array)

When like this, each antenna is receiving the same *PHASE* signal. The voltage goes up and it goes down at the same time in both antennas.

Now, slightly rotate this array so one of the antennas gets its waves a bit earlier. It will receive an *advanced * phase. The further apart these two antennas are, the more sensitive it will be to a small angle of rotation. Making your "D" bigger will make the antenna array "see" more phase shift for the same small angle (hat it is turned, right?

Also, if the signal comes from a slightly different direction, the same thing happens and therefore it can *RESOLVE* direction better with a larger "D".

Help any?

Better.

As I said, earlier, This thread has drawn me back to re-reading "Zen
and the Art of Motorcycle Maintenance". If you haven't read it, I
highly recommend it.

Here is a passage that jumped out at me, last night.

"The real purpose of scientific method is to make sure
Nature hasn't misled you into thinking you know something
you don't actually know. There's not a mechanic or scientist
or technician alive who hasn't suffered from that one
so much that he's not instinctively on guard.
That's the main reason why so much scientific and mechanical
information sounds so dull and so cautious.
If you get careless or go romanticizing scientific information,
giving it a flourish here and there, Nature will soon
make a complete fool out of you. It does it often enough anyway
even when you don't give it opportunities.
One must be extremely careful and rigidly logical
when dealing with Nature: one logical slip and an entire
scientific edifice comes tumbling down. One false deduction
about the machine and you can get hung up indefinitely."

Use both programs and compare the results.

Make the coil 1 metre long, 500 turns, and diameter 25.4 mm (1 inch).
Give the programs something to get their teeth into.

How does EZNEC make its calculations? If you don't know you are
placing your faith in a mirage.

Now there's a commendation for your own work. No wonder we don't see
any correspondence from you with actual values for the coils offered.

Lords Plushbottom and Kelvinator might let you serve in the black
gang, moving coal on one of those transatlantic cable layers - but
they certainly wouldn't expect a practical answer to:

"How many shovels full today Reggie?"

"If your lordships will forgive me, but you can find out by
downloading my unzipped SHUVFULL.EXE and entering many fascinating
variables."

"I say, Plushbottom old son, we must ask the Boatswain to check
the coal bunkers for hidden bottles of Sack."

Who would've guessed that the comedic possibilities still lingered
after 600 postings. ;-)

It's hard to tell from this, but are you still claiming that the
end-to-end C of an inductor is the C of an equivalent transmission line?
Or even an approximation? Does your program assume this?

A bit more than a mirage -- you're placing your faith in a program (NEC-2) which has been in daily use by hundreds to thousands for nearly 30 years, and has been used for designing countless antennas, several of which you almost certainly use daily.

But anyone interested in knowing how EZNEC does its calculations can get a highly detailed answer from the NEC-2 manual, available free at http://www.si-list.org/NEC_Archives/nec2prt1.pdf. Or, if interested in the general method (method of moments), there's a very good and easy to understand explanation in the second and later editions of Kraus' _Antennas_. I'm sure there are some good (and undoubtedly also bad) explanations of the moment method on the web, also.

Cecil,

I don't remember why you chose a frequency of 5.89 MHz for all of your analysis, but in any case I believe that frequency is slightly out of the 75 meter band. The FCC will be calling. 8-)

I tried to adjust the frequency downward, but the segment length limit is reached for the coil model. I redrew the coil with only six segments per turn, rather than eight. Now the frequency can be lowered to about 3.94 MHz without EZNEC guideline check warnings.

In order to get the 90 degree phase curve I extended the horizontal wire to about 55 feet. (not sure why this matters if the antenna is purely a terminated traveling wave antenna, but, hey, no loose ends.)

The result from EZNEC is that the phase shift in the coil is about 9 degrees.

You might observe that this shift is a bit smaller than the "tens of degrees" noted below, and it is also smaller than the guru-inspired transition point of 15 degrees.

I would like to model a coil more typical of common use than the strange beast you designed, but the segment length limits in the NEC engine seem to preclude such models. (I have never seen a mobile coil that is 12 inches high, 6 inches in diameter, with 2 turns per inch.)

If I was the cynical sort I might think that your choice of coil dimensions and frequency were picked to get a phase shift of 16 degrees, which is just over the guru limit. But since I am a straightforward kind of guy I won't think such thoughts.

73,
Gene
W4SZ

Aperture is the same as capture area. Both are the same thing as gain (although numerically different), just looking in the problem in the reverse direction. Once you know the gain, you know the aperture and capture area or vice-versa.

> . . .

Of the Guideline Check warnings, the one about short segment length can most often be ignored without a problem. If in doubt and where practical, do a test case. For example, model the inductor with a wire through the middle directly connecting top and bottom and with a source in the middle. Note how the source reactance changes with frequency to see that it follows what it should theoretically do. Another test you should run when in doubt is the Average Gain test, described in the manual. Either is probably adequate to have confidence in the results.

The Guideline Check warnings are based on NEC-2 recommendations. I've found that you can often make segments much shorter than the recommendations without causing a problem.

It uses the Moment Method (MM) sometimes called the Method
Of Moments (MOM). It's described in Kraus and Balanis
and credited to Roger Harrington in the 1960's.

Each segment in EZNEC is assumed to have constant current.
In the aforementioned 8-sided coil, there are 200 segments,
each with an assumed constant current. The standing wave
current in each segment depends upon where it is inserted
in the standing wave environment as shown at:

:-) Here's the history. I tried to model my 75m bugcatcher coil in
EZNEC. It appears to be impossible without violating EZNEC's guidelines.
So I changed the coil from 4 TPI to 2 TPI. That moved the resonant
frequency from 3.8 MHz to 5.9 MHz, close enough to the 60m band
that I thought no one would object. Do you think the FCC calls everyone
who uses EZNEC to model an antenna out of the amateur bands? :-)

Hey, great.

> In order to get the 90 degree phase curve I extended the horizontal wire
> to about 55 feet. (not sure why this matters if the antenna is purely a
> terminated traveling wave antenna, but, hey, no loose ends.)

I found the same thing. Seems no matter how one changes things, it
appears to be a diverging series. The main goal is to get the reflections
reduced to a low level, maybe not to eliminate them entirely.

> The result from EZNEC is that the phase shift in the coil is about 9
> degrees.

Yes, but that's for a coil designed for a 6 MHz antenna. You need to
add a lot of turns to make it typical of a 4 MHz coil. Doubling the
turns would make for an 18 degree phase shift - a detail you seem to
have missed. Please expand the coil until it resonates an 8 foot
antenna on 4 MHz and repeat your findings.

> You might observe that this shift is a bit smaller than the "tens of
> degrees" noted below, and it is also smaller than the guru-inspired
> transition point of 15 degrees.

Of course, a 60m mobile coil used on 75m is going to have a smaller
phase shift. But you dropped a bit in your logic, Gene. What you need
to do is go back and create a coil that resonates an 8 foot antenna
on 4 MHz. Then do your phase calculations. When you do that, the delay

in the larger coil will turn out to be tens of degrees. Could you email
me your EZNEC file? (Hopefully, without the worm/virus I received from
someone else recently.)

> I would like to model a coil more typical of common use than the strange

We do the best we can do with the tools we have. Actually, I
have seen such a coil at one of the CA 75m shootouts. It was
made out of half-inch copper tubing.

> If I was the cynical sort I might think that your choice of coil
> dimensions and frequency were picked to get a phase shift of 16 degrees,
> which is just over the guru limit. But since I am a straightforward kind
> of guy I won't think such thoughts.

I tried to model my 4 TPI 75m bugcatcher coil. EZNEC would have
none of that. So I modeled what I could. The phase shift of
16 degrees was a complete coincidence, but interesting, no?

The problem that Gene and I are having is the spacing between
adjacent segments. EZNEC won't allow me to do a 4 TPI coil.

Source record: 62319

Hi Roy,

Thanks. I went back and bravely ran the original coil model, ignoring the guideline checks. The difference in results from the two coil models, eight-sided and six-sided, was in the noise. (Or at least well below the new RRAA error guideline of 59%.)

Emboldened by this apparent success I tried to substitute the now-famous W8JI coil; 100 turns, 2 inch diameter, 10 inch length. This time the overall 500 segment count was the limiter (I am cheap), so I had to make the coil four-sided. The delay through this coil was about 9 degrees at 5.89 MHz and about 6 degrees at 3.9 MHz.

Sooooo, the bottom line for the 17,000 posts in this thread is that the pure lumped-circuit toroidal coil analog might be just a slight bit stingy, but it comes pretty close to reality. The full-bore transmission line model for the coil works as well, but it does not appear to add much useful information. The real phase shifts are well below the 15 degree transition point claimed by the Tesla coil crowd. I am sure none of this is news for you or for most others.

Cecil has thanked me on several occasions for bringing up the standing wave equations. I now must return the favor by thanking him for setting up the traveling wave model. It did not prove his point, but it helped bring clarity to the issue.

I am confident that this will not be the end of this immortal thread, but it is now quite clear through simulation that the entire issue is much ado about very little.

Uhhh Gene, you still need to add turns to the 6 MHz coil to bring
it down to 4 MHz with an 8 foot antenna. No fair reporting the
half of the results that agree with your preconceptions while
ignoring the half of the results that disagree.

You wish that was the bottom line. Here's some mud in your eye.

1. I have always been talking about my 75m bugcatcher coil which
is about 6"x6" and designed for actual mobile use. W8JI's coil
is nowhere near what the average ham uses for a 75m bugcatcher
coil. It is much too fragile for long-term mobile use. It can't
even be considered to be a "bugcatcher" because one Texas-
sized bug and it is destroyed.

2. You haven't installed that coil in an 8 foot 75m mobile
antenna so you don't know what the delay is in an 8 foot
4 MHz system. Please feel free to try again - no cigar at
the present time.

My 75m bugcatcher coil has to be attached to a 75m mobile antenna installed on my GMC pickup. That's the boundary conditions and I have been explicit about that. This is getting stranger and stranger. Next you guys will have the coil floating in free space between Sol and Alpha Centauri unconnected from anything in order to remove it from any resemblance to a real-world environment.

In virtually all my postings, I have specified that I was talking about a 75m bugcatcher coil installed in a mobile installation. It really doesn't matter what happens outside that specified environment.

The gurus are slowly divorcing themselves from reality. The only way they can be right is to take the mobile antenna off the vehicle, throw away the antenna, and keep the coil for testing on a bench. Have you no shame? How far are you willing to retreat from reality to make a feeble attempt to be right?

Cecil,

I thought we already agreed that there is no phase shift in the real environment, namely, a nearly pure standing wave environment. You were the one who brought up all the special cases in an attempt to prove your point.

However, your latest message is refreshing. I was afraid for a while that you were attempting to use a 48 foot tall mobile antenna or drag a 31.5 foot wire terminated in a resistor down the road.

73,
Gene

You are not arguing in good faith.

We agreed that standing wave current with its unchanging phase
cannot be used to measure the phase shift through a coil. The
fact that there is no phase shift from end to end in a 1/2WL
thin-wire dipole proves that using the standing wave phase
to measure a phase shift is meaningless. You said the same
thing in the following statement. Do you want to retract what
you said?

Regarding the cos(kz)*cos(wt) term in a standing wave:

Gene Fuller, W4SZ wrote:

No, I'm using your posting to prove that standing wave current phase
is meaningless. There's no special case. Standing wave current phase
is *always* meaningless.

Please install your coils in an 8 foot 75m antenna and get back to
us on the results.

Roy,

What do you mean by end-to-end C.

But very recently you did say "Reg is right" when I said "All coils
behave like transmission lines."

You and I agree on most fundamental matters.

Reg.

In your last posting, you asked "How does EZNEC make its calculations?" Wow, you're a quick learner.

> But do you know how it calculates the inductance of coils?

Yes. A model of a coil is constructed out of straight wires, making each turn polygonal. A wire containing a source is connected from one end to the other and, providing that the coil is short in terms of wavelength, the reactance seen by the source will be that of the coil at the test frequency.

> How long has it been able to do this?

An automated helix creation feature was introduced in v. 4.0 two years ago this May. It has always been capable of doing the calculation, but until v. 4.0 the user would have had to calculate the wire end coordinates with an external program and import them into EZNEC.

The free demo version has this feature. You can create any size helix with it to see how the feature works. You won't, however, be able to calculate its inductance with the demo program due to the segment limitation.

As I've pointed out before, EZNEC won't account for proximity effect, so reported loss will be optimistic if the turns are spaced very closely.

I've a feeling there is some confusion here between phase delay in
degrees, and delay in time (nano-seconds).

The former changes with frequency. The latter does not.

You should all make yourselves perfectly clear.

What most people would call "self capacitance" -- the equivalent
capacitance from one terminal to the other.
>
> But very recently you did say "Reg is right" when I said "All coils
> behave like transmission lines."

More specifically, you said:

> EVERYTHING has Inductance, Capacitance and Resistance, and therefore
> behaves as a transmission line.

I agreed with that. This doesn't mean that I agree that you can choose
any C you like from any point to any other, plug it into a transmission
line formula, and get a meaningful result. Transmission lines are two
port, four terminal devices, so a completely isolated inductor or other
component, by itself, can't behave as a transmission line, except by
assuming some C to the Earth.

> You and I agree on most fundamental matters.

I'll have to take your word for that. It isn't always apparent by what
you say in your postings.

I don't think EZNEC cares about the inductance of helical coils. As I have been advocating, the EZNEC helical option treats the coil as just another part of the wire antenna that has been spiraled into a coil.

It is ironic, is it not, that EZNEC treats a helix as just coiled up wire? Especially after the gurus have asserted that a coiled up piece of wire is not a piece of wire at all but is instead transformed into something magical that violates the theory of relativity with faster than light propagation?

> How long has it been able to do this?

I don't know exactly. I was creating segmented coils long before EZNEC had the helix option. I even wrote a BASIC program to generate an ASCII file capable of being imported into EZNEC.

EZNEC takes a time-frozen snapshot of the system and reports the
phases throughout the system referenced to the source.

So, given a 1/2WL thin-wire dipole, what is the difference between
the delay in nanoseconds and the phase delay in degrees. Aren't
they convertable to each other?

Some mobile phones (Ericsson) can be keyed to present the "real" signal strength, not only the blobs on your LCD but a Signal Strength number.

Perform a Google search and see what you can find.

Cheers

The capacitance of a coil is to the second "wire", that is, to the "rest of the universe".

I forget the name of the current which flows through that capacitance. But undoubtably, it does flow.

Apart from end-effects (as with an antenna wire) it is uniformly distributed along a body (as with a transmission line) and is sufficiently accurately calculable.

The whole capacitance has an equivalent capacitance which can be connected between the ends of a coil to make a resonant circuit with the coil isolated in space. There is a resonant frequency.

But no use can be made of the resonant frequency because as soon anything is connected to either one or both ends of the coil the capcitance to the rest of the world changes and the resonant frequency shifts downwards. I could go on!

But Roy, you know all this and I mention it here for the benefit of novices.

There's no phase shift in the standing wave current in 45
degrees of straight wire. Doesn't that tell you something?
You said yourself that the standing wave current phase
doesn't contain any phase information.

Here's what you guys need to do to convince me that you are
right.

1. Develop a coil acceptable to EZNEC that resonates an 8
foot whip on 4 MHz over mininec ground. Send me a copy of
the EZNEC file.

2. Put the same coil in the traveling wave environment as
I have done at: http://www.qsl.net/w5dxp/test316y.GIF
and report the phase shift through the coil. Send me a
copy of the EZNEC file.

If you are so right and I am so wrong, that shouldn't be
too difficult for half a dozen gurus (including the
developer of EZNEC).

Of course they are, you block-head. But one is measured in degrees of
phase-shift and the other in nano-seconds of time. So to prevent
confusion you must say which one you are waffling about.

Cec,

Having clarified what *I* am waffling about, are *you* still saying
that EZNEC reports propagation delay as being dependent on frequency.

Is it phase delay or time delay along the coil which is dependent on
frequency?

If the question is how is EZNEC reporting it's results the person to ask the question of and the only person who can give a definitive answer is the author of the program. What process did he use in writing the program. A computer program, any program, can only give the answer in terms it is programed to use, using the mathematical formula that is coded into the program. Even R2D2 could only respond according to it's programming.
Let's quit attempting to split hairs and look to the original program for the answer.

> So would be interested in your comments on Antenna aperture and antenna gain
> and capture area

If you have an antenna of a known type that happens to be
area-dependent on gain, you could tie gain to physical size (physical
aperture) through a formula.

That isn't to say the relationship holds in anything other than a
specific case. For example if the dish is not formed correctly gain
with drop, despite the dish being a size that would otherwise have
higher gain. This means the capture area would be smaller than you
calculated for a "good dish".

Same for feed system. If the illumination system blocks the area of the
dish or has design flaws, and if gan drops, the effective aperture
would be less for the same size antenna.

Does this make sense to you?

Then that's a big problem.

Unless the outside of the cable has the same Vf as the inside, the sections won't have the correct phasing.

Phelps Dodge did that two ways.

First, when they used solid dielectric coax, they filled the antenna with a very thick wax that gave the correct Vf on the outside of the shield.

Second, when they used air insulated coax inside, they suspended the coax in air with only an occasional piece of foam for spacing.

There is more to this antenna than just throwing some .66vF sections in series! Every coaxial collinear I have built and measured from articles in Ham mags has had virtually no useful gain at zero degrees angle over a dipole.

I picked up a 1:1 balum at a local hamfest, i got it because it had a N connector and thats the type of connector on my coax. After looking closer i thought it was a 10-40 meter but i
cant make out the print, it may be 10-40mhz.
I desided to open the pvc to find out just what was inside, I found a bunch of ferrite disk stacked over the coax, this wasent my idea of a 1:1 balum. I hoped to make a 160-10 meter
dipole/inverted vee using the proper length wire on each leg for 160,80,40 & 10. My question
is this, will this work at lower frequencys 160 & 80m ? If not what the purpose of the ferrite
disks, it seems that i could just remove the disk if they limit the frequency range, i guess
im trying to inderstand what makes this a balum & what purpose the disk serve?

EZNEC doesn't report time or propagation delay. If it's needed, it must be calculated from the reported phase angles.

You have what is commonly known as a W2DU 1:1 balun-choke
made popular by Walter Maxwell. It's probably not very
effective on 80m and 160m because of the choice of
ferrite materials.

In my case, done by installing zero ohm loads at the bottom
and top of the coil for the traveling wave antenna.

Cecil,

I have sent the files to you, as requested. The resonant whip ended up at about 10 feet, not 8, because I tired of the continuing the optimization. The phase shift found from the traveling wave version was about 7 degrees. The coil was similar to the coil you have been using, except squeezed down to 6 inches tall, 4 TPI. You can refine the models or perform the required adjustments as you wish to get the 8 foot version. I would not expect radical changes, but who knows?

It is always possible that I made a mistake in the modeling. If so, I am confident the entire world will know in short order. 8-)

73,
Gene
W4SZ

==========

EXACTLY! Roy, you knew exactly what I was hunting for!

The phase angle should indeed increase with frequency.
With a true transmission line the increase should be directly
proportional to frequency.

But the propagation delay, with a true transmission line, should be
constant versus frequency as it depends only on coil dimensions and
hence on L and C. The velocity factor should also be a constant.

When the angle is 90 degrees the coil is 1/4-wave resonant.
When the angle is 180 degrees it is 1/2-wave resonant.
The 180 degree frequency should be twice the 90 degree freq.

The differences between the 'measurements' and expectations, on the
basis of a true transmission line, can perhaps be explained by the
very small ratio of wire diameter to winding pitch. (Who would use
such a coil to load an antenna anyway?)

The ratio of coil diameter to coil length is large. Therefore
end-effect (as with an antenna wire) becomes quite important.

I have no idea what else may have been 'connected' to the coil when
inside EZNEC. Could it have affected measurements? Would it be
possible to 'measure' input impedance looking into one end of a coil
with the other end disconnected?

Regarding the calculated values of delay time there seems to be
something wrong. There is a simple relationship between phase angle
and length of coil and time. What was the formula used to calculate
propagation time? If the correct formula was used does this point to
somthing peculiar with EZNEC's own calculations?

Can't think any more.

Reg.

Glad you asked. I calculated (1/f)*(angle/360) or period of one cycle times fraction of a period. I assumed that all the phase shifts given were less than one period, total. I was hoping someone else would calculate the delays and correct any mistakes in my method or results.

>If the correct formula was used does this point to
> somthing peculiar with EZNEC's own calculations?
>
> Can't think any more.

Or it points to the coil in question not acting purely like a transmission line over this range of frequencies. How would a short length of transmission line act if you parallel it, end to end with capacitance? This coil certainly has end to end capacitance.

At some high frequency, that capacitance will, first resonate with the inductance, forming a trap (with a rapid phase change with respect to frequency), and above that, bypass the antenna current around the inductance. At very low frequencies, with a low impedance on each side, almost pure inductance probably dominates. In between these, (with appropriate impedance connections), there is probably a frequency range where it acts mostly like a short piece of transmission line, with approximately (a lot less approximate than +-60%) constant delay.

In such a large beast, at the intended frequency of operation, unintended parasitic effects may be as big as the intended inductive effect. These are the problems that make designing good (as in, "act as lumps of inductance") coils interesting.

If you can get an ohm reading when you touch the two probes of an ohm meter to the ferrite, then it is probably a low frequency, high permeability manganese zinc ferrite, and may produce enough common mode impedance to act effectively as a 1:1 balun in this frequency range.

If you measure an open circuit, it is almost certainly higher frequency, lower permeability nickel zinc ferrite and will produce insufficient common mode impedance to be effective as a balun in this frequency range.

wrote:

>What most people would call "self capacitance" -- the equivalent
>capacitance from one terminal to the other.

Hi Roy,

Not strictly speaking. It ("self capacitance") is with respect to a
very remote reference, not merely the two plate formulation of the
terminal's geometries to each other (that is more part of the
distributed capacitance).

There are two measures of capacitance. Self capacitance is any body's
capacity to store charge. You don't need a second plate to do that in
the classical math - merely a reference point from which the voltage
is determined (yes, another dimensionless oddity that makes this more
easily said than done). Mutual capacitance, two plate construction,
is the more usual form we all have come to expect - so much so that
the term mutual has fallen into disuse and most express only the
second, isolated term - capacitance.

Tom, a week or so back, asked about the infinitesimal capacitance of a
coil with 15 meters (or so) of wire. He speculated that as the
"second" plate of the (mutual) capacitance was withdrawn to infinity,
that it forced the value to zero. I, on the other hand showed that in
the practical universe:
>> C = 2 ï¿½ Pi ï¿½ epsilon0 ï¿½ L / (ln(b/a))
>>a = 1m (after all, thin is relative at infinite dimensions)
>>L = 15m
>>b= 1,000,000,000,000,000,000,000,...000m (10ï¿½ï¿½ï¿½ meters away)
>>epsilon0 = 0.00000000000885
>>
>> C = 12 femtofarads
>>
>>This was certainly at the limits of my usual Capacitor Bridge to
>>measure to this resolution 30 years ago, but time has marched on. This
>>sized capacitance is certainly encountered every day in my new field
>>of nanotech, and 1 femtofarad is measured by charge transfer
>>techniques.
>>
>>Consider, Einstein's estimate of the radius of the Universe is roughly
>>10 Billion Light Years (ï¿½3dB) As this result above is vastly further
>>away than Einstein's guess (by more than 300 orders of magnitude),

>>
>>Oddly enough, this value is on par with the distributed capacitance of
>>the coil's we've been pounding away on (and even more convergent, is
>>this is roughly the same amount of wire used in them).
>>
I extracted this correlation from reports of the coils' self resonant
frequency and their inductance.

Self Capacitance is nothing more than Mutual Capacitance with a second
spherical plate, with a radius of this 10 Billion Light Years.
However, this capacitance is the total bulk of the coil rather than
that distributed to form a transmission line.

Anyway, thinking of a coil in terms of Mutual Capacitance, Distributed
Capacitance, Self Capacitance, Self Inductance, and Mutual Inductance
is a tantalizing prospect to investigate and elevate the topic to this
mythic status of transmission line - but I seem to lack the motivation
to go there. The extraordinary farce is more entertaining.

Hi All,

I am a SWL from India and hope to get a ticket soon. I am constructing a simple receiver and i would like to construct a good antenna for my receiver and in future for my transmitter as well. I came across a design in a souvenir released by Hamfest India where an antenna called "Pyramid Antenna" is described. The author gave reference to one design published in Radio Magazibe 1982 by Steve Bauer,DJIUS. I came across another similar design described in http://www.warc.org.uk/clubmag/qsx13.pdf . I would like to know more about this antenna and the experience of using it, and about it's performance. My house is near a 11KV power line and my antenna will be less than 15 feet from the above said power line.

Thanks in advance.

Regards
Shan

A close-up of the photo shows four horizontal wires, though not necessarily parallel, and three vertical elements I believe are supports. The horizontal wires are probably connected to each other through those vertical elements. It is possible that the antenna is one long wire woven into that butterfly shape you see in the photo.

It is also possible that EZNEC cannot be used for this task.
It doesn't make technical sense that the delay through a
coil can go from 7 nS at 5.5 MHz to 38 nS at 12 MHz. I
think that was what was bothering Reg.

You didn't measure the time delay through the coil. There is
zero phase change in the standing wave current and the SWR in
your circuit was ~16,000:1. The only way I can think of to
measure the actual delay through a coil is in a traveling
wave environment, not a standing wave environment. No one
has tried to measure the coil delay in a traveling wave
environment.

One more time, the standing wave current phase is unchanging
over every 1/2 wavelength of antenna. At the 1/2WL points it
changes abruptly by 180 degrees.

If you locate a standing wave node inside the coil, you will
measure a 180 degree phase shift through the coil.

It is used to reduce the common mode current which sometimes flows in coaxial and balanced-pair lines.

It is not a transformer. The 1-to-1 is meaningless. It is just a pair of wires wound together, as one wire, on a ferrite core. Or in your case a number of ferrite slugs or rings are placed over a coax line.

In brief, it is just a choke.

Reg.

Once again Cecil's famous selective editing allows him to remove things
from context and change the results to suit his unusual ideas.

The sad part is now I'm positive Cecil knows exactly what he is doing.
I know that because it was explained here in this thread what the
measurements were, and he understood the data.

This is why I think getting into a long technical discussion with Cecil
is a waste of time. He will selectively edit any exchange to suit his
needs, and then the whole thing has to be repeated.

I have no experience with this antenna but I always recomend a 1/2
wave dipole to start with. It is more likely than any other antenna to
give good results under all conditions. Save the complicated things
for later!

Having said that, I must add that I would not install ANY antenna only
15 feet from an 11 KV transmission line!

There has to be another way.

But a choke with two wires wound through it is two inductors that also
have mutual inductance between them, and if that doesn't define a
transformer, what does?

It is true that this device acts as a choke for common mode current
(the component of the two currents through the two conductors that is
in phase). A choke is an inductance, which produces voltage across
the terminals of the conductor passing through that is proportional to
the rate of change of the current. In this case, it produces a
voltage across both the shield section inside the cores and also
across the center conductor inside the cores, that is proportional to
the rate of change of the common mode current. It is this voltage
that alters the displacement currents in the two terminals at the
antenna end, to make them look like a more balanced signal, and at the
transmission line end, more like a single ended one.

Hi John,

Then you think of it as an air core transformer with series driven,
bucking sections. Now, what kind of practical transformer does that
define? 1:1 does not automatically spring to mind unless it is
isolating one circuit from the other. However, it is not the
transformer that does that, it is the choking ferrite and only in the
service of snubbing common mode currents.

With this in mind, do we add a characteristic of loss to the
definition? A lossy air core transformer with series driven, bucking
sections.

You are bordering on stretching the definition of power transformer
over the application of a BalUn. This is not always useful. So, what
does it transform? A balanced circuit to an unbalanced circuit (or
versa vice).

Air core? It is a ferrite core transformer with two one turn
windings. One winding is the shield passing through the holes in the
cores and the other winding is the center conductor passing through
the windings. (view with fixed width font, like Courier)

```
|half of dipole
. |
Center cond.-----MMMM-+
.
Shield-----------MMMM-+
|
|half of dipole
```

MMMM represents a transformer winding.

On the left side, essentially all the voltage is on the center
conductor, and on the right side, half of that voltage is on the top
side of the dipole, and its negative is applied to the bottom side.
So half of the instantaneous voltage of the center conductor just to
the left of the transformer appears across each of the transformer
windings. It is a 1:1 voltage transformer. That half is subtracted
from the center conductor voltage and added to the shield voltage.

If the individual winding inductive impedance is high at the frequency of operation, it has the effect of forcing the total instantaneous current through the pair of windings to be very low. But it also allows, with almost total transparency, that the instantaneous current through either conductor can be any value, as long as the it is canceled by an equal and opposite instantaneous current through the other winding. So it enforces equal and opposite currents in the two conductors, which is exactly what you want in a coax and a dipole, while allowing the dipole voltages to be equal and opposite, but all the voltage to appear only on the center conductor of the coax.

> You are bordering on stretching the definition of power transformer
> over the application of a BalUn. This is not always useful. So, what
> does it transform? A balanced circuit to an unbalanced circuit (or
> versa vice).

Unbalanced on the coax side, and balanced on the dipole side. If the dipole were not balanced, the currents in the two legs would not be equal, and this current mismatch would cause the transformer to produce more or less voltage across the windings, in the direction that forces those two currents to be more equal. This thing is not nearly a classic transmission line balun, but is quite nearly a classical 1:1 transformer.

I mainly wanted to know if it would work on 160 & 80m, I dont care
if it acts like a choke/balun only at higher frequencys as long as
as it doesnt interfere with 160 & 80s swr. Normally i just use coax
hooked to each leg cut to frequency, without a balun. Its allways
worked in the past years, i just thought it would be alot easier to use
the ready made balun than try and makeup a weatherproof
hanger

Seems to me there are two things of major concern. 1- getting close to the target and and 2- phase wrap.

Anyway...
How do they actually distinguish phase in the GHz range between two dishes across the country/world? I heard they use recordings, but that can't be right since they'd need pico second timing accuracy...

It should not interfere. If the ferrites don't have enough reactance
to make it act as an effective choke on 160/80, then it'll just "look
like" a foot or two of coax to the signals.

Most of the people that died in the Hindenburg disaster were killed by
burning diesel fuel, which radiates lots of heat, key word being radiate.

Burning hydrogen is fairly safe to stand in the middle of, as long as
you have an air supply, since it does not radiate in the infrared range.
And before someone responds, a hydrogen torch would be different, and
was not the case here.

Those not killed by the diesel fuel, or other non-hydrogen burning items
were killed by the fall.

Hi John,

If there's a transformer in the sense of windings; then it is an air
core, the ferrite is wholly transparent to the transverse currents.
You could remove the ferrite and it wouldn't make a bit of difference
in that sense of transforming.

>this current mismatch would cause the transformer to
>produce more or less voltage across the windings
In fact, nothing of that sort happens - at least not by your
description. The ferrite is simply bulk resistance inserted into the
common mode path. That is why common mode current is suppressed. The
same thing occurs in the coiled transmission line choke, but the
resistance is replaced by reactance. Again, common mode current is
snubbed by encountering this too.

The transformer property is in the isolation of the balanced circuit
from the unbalanced circuit through this resistive characteristic.

You are missing one path. The two from the source in the form of the
inner shield of the coax, and the center conductor, and the one from
the load in the form of the outer shield of the coax (same shield, but
isolated circuits). Further, there is no flux linkage of the two
conductors coming from the source. Their magnetic lines never break
the cores, whereas the common mode current does break the core which
thus inserts the resistance of the ferrite.

I have a 200ft tall Rohn 25 that has handled 1/2 radial inch of ice. It has also handled winds over 100 MPH several times.

It is properly guyed to Rohn specs. It is also 25G.

I see quite a few people who think they have 25G when they really have Rohn 20.

Rohn 20 and 25 look the same and actually fit each other, except Rohn 20 is thinner wall and has fewer cross braces.

I used to be systems engineer for a company that had several dozens of CATV antenna systems. We had dozens of sites with 50-100 feet of Rohn 25 loaded with a microwave link antenna and a few TV antennas. In every single case of a tower failure, it was due to a guyline being installed incorrectly. Either clamps on backwards, wrong style turnbuckle, or other hardware problems were most common. When the guys were installed correctly, the towers would last forever. I remember one that was standing (stripped of antennas by a tornado) and the apartment building next to it had no roof left!

I said that. It is a common mode transformer.

> You could remove the ferrite and it wouldn't make a bit of difference
> in that sense of transforming.

The short length of the two conductors passing through the ferrite is
certainly a poorer transformer (less mutual inductance between them)
if you remove the cores.

>>this current mismatch would cause the transformer to
>>produce more or less voltage across the windings
>
> In fact, nothing of that sort happens - at least not by your

Make that, "impedance (mostly inductive, if the ferrite is well suited
to the frequency)" and I agree.

> That is why common mode current is suppressed. The
> same thing occurs in the coiled transmission line choke, but the
> resistance is replaced by reactance. Again, common mode current is

I agree with this, except that the purpose of the ferrite is to
increase the common mode inductance of the section of coax passing
through it, not add resistance. Some resistance is inevitable,
because no ferrite is lossless, but the intention is for inductance.

> The transformer property is in the isolation of the balanced circuit
> from the unbalanced circuit through this resistive characteristic.

Try transmitting through such a resistance and you are going to lose a
lot of your power.

> You are missing one path. The two from the source in the form of the
> inner shield of the coax, and the center conductor, and the one from

> the load in the form of the outer shield of the coax (same shield, but
> isolated circuits).

I can't parse this. There are two metal conductors entering the
choke, and two exiting it. All currents pass through those 4 conductors.

> Further, there is no flux linkage of the two
> conductors coming from the source. Their magnetic lines never break
> the cores,

I think you mean by this that a normal unbalanced signal in a coax has
no magnetic field external to the shield. It is all between the
center conductor and the shield. And I agree that this is what you
are trying to accomplish by adding this two conductor choke between
the coax and the balanced antenna. Without it, there would be some
magnetic field from a net (uncanceled) current and voltage on the
outside of the shield that would cause the coax to radiate. And the
voltages and currents fed to the balanced antenna would not be equal
and opposite (balanced) but somewhat unbalanced. There would also be
non equal currents in the center conductor and shield. I think we
agree on all that, but have a different picture of how a choke balun
corrects these problems.

> whereas the common mode current does break the core which
> thus inserts the resistance of the ferrite.

The common mode current causes flux in the core, and the conductors
passing through that flux produce a voltage proportional to the rate
of change of that flux, just as the conductor passing through any
inductor would. The transformer aspect is that since both conductors
pass through the exact same rate of change of flux, there is the same
voltage produced at the ends sticking out of the core, and this
voltage gets algebraically added to what is already there. If the
inductance of each winding is high enough (5 to 10 times the coax
impedance) a very small common mode current is enough to produce a
large enough voltage across the ends to the two conductors to correct
most of the unbalanced to balanced coupling.

Admittedly, there is no need to get this inductance (including mutual
inductance) with the aid of ferrite around the coax. You could just
wind the coax into an air core transformer. But it would be
considerable larger than one made with a high permeability core,
though, probably lower loss.

"Low frequency" ferrites are well suited to applications as HF chokes and broadband transformers. What you don't want to do is use them for a high Q inductor in a filter, tuned circuit, or similar application.

Baluns work fine with a resistive impedance, with the exception of applications involving large power. In fact, resistive impedance is desirable because the impedance changes little with frequency, and is relatively free of resonance effects. (More below.)
>
>> The transformer property is in the isolation of the balanced circuit
>> from the unbalanced circuit through this resistive characteristic.
>
> Try transmitting through such a resistance and you are going to lose a
> lot of your power.

You're not "transmitting through" a balun's impedance. Only the common mode current effectively flows through it, and the power dissipated by the balun is Icm^2 * R, where Icm is the common mode current and R is the resistive part of the balun's common mode impedance. If R is small, dissipation is low. But if R is large, that makes Icm small, so dissipation is also low. It's really an impedance matching problem when the balun is resistive -- a very low or very high balun R results in low dissipation. Dissipation is maximum at some intermediate value of R and decreases on each side.

A typical balun made with "low frequency" ferrite (e.g. Fair-Rite 70 series) and operating at HF or above (and therefore primarily resistive) having a common mode impedance of 500 ohms or greater generally won't dissipate any significant fraction of the transmitted power. However, if you're running high power, even a fraction of a dB dissipated in the balun will cause it to overheat. Consequently, people running high power often resort to type 43 ferrite (a Fair-Rite designation; or its equivalent from other manufacturers), which is less resistive than lower frequency ferrites. In extreme cases, high frequency (60 series) ferrite is necessary. The problem is that it's increasingly difficult to get adequate impedance with the higher frequency ferrites. Type 43 is often a good compromise, and it's widely available in many core sizes.

> different picture of how a choke balun corrects these problems.
> . . .

Common and differential mode currents are physically separated in a coax cable, and so are the fields from the two components, providing that the shield is at least several skin depths thick. The differential mode current and its fields are entirely inside the coax, decaying rapidly as you go outward from the inner boundary of the shield. By the time you reach the outer boundary of the shield the fields from the differential current is negligibly small. So any core you put over the coax doesn't see or interact with the common mode current or its fields at all, and you can completely ignore it when analyzing balun action. Similarly, you can ignore the core when analyzing the differential mode properties of the system. The common mode current resides in a thin layer on the outside of the shield, it and its fields never reaching the inside. The balun provides an impedance to this current just as it would to any current on the outside of a conductor.

When bifilar wound, the fields from the differential mode current are primarily between the turns, although some relatively small amount extends beyond to interact with the core. The net result is nearly the same.

Roy probably meant "differential" above instead of "common".
Cores on coax definitely "interact with the common mode current
or its fields" and that is their purpose.

Thank you John. My dad is a HAM and his call sign is VU3SMX. He is not
active on the band nowadays because of his age, 70 years. I used to
help him erect antennas and we had experience with inverted V antennas.
In our previous QTH we didnt have any problems with the erection of
antennas, because we had ample space.
My new QTH is in Bangalore and this antenna came from another Indian
HAM Kannan (VU2KBX) who used this type of antenna in noisy conditions.
He is an Electrical engineer and lives near to a Electrical-Substation.
Iam sending the said article to you to your mail id:
johnferrell@sprintmail.com for your reference. Thanks again for the

help.
Regards
Shan SWL.

Hi John,

No, the principle of the impedance is overwhelmingly resistive, not
reactive. One core (#75) that snuggly fits over RG58, at about 10MHz,
exhibits 25 Ohms resistance to common mode current. My BalUn uses 50
such whose combination presents 1250 Ohms resistance. This value
varies over frequency, but easily finds a 1000:50 ratio over the
entire MF/HF Ham spectrum.

I also have two engineering samples boxes full of various material
types and geometries and have measured them all. Some exhibit
reactance, but are vastly overwhelmed by their intrinsic resistance.

>> That is why common mode current is suppressed. The
>> same thing occurs in the coiled transmission line choke, but the

Quite the contrary. Inductance, or more properly to the application,
reactance, may come as a consequence of these cores, but that is
really just a minor component to the vastly greater resistance.

>> The transformer property is in the isolation of the balanced circuit
>> from the unbalanced circuit through this resistive characteristic.
>
>Try transmitting through such a resistance and you are going to lose a
>lot of your power.

That power, actually current, was forced into a common mode because of one of several problems:
1. Massive imbalance in the radiator design,
2. Massive catastrophe with the radiator.

If you are destined to "lose a lot of power" into such resistance, you have far greater problems you are ignoring. However, let's return to this "loss of a lot of power." You have an antenna with a nominal 50 Ohm load resistance (presumably balanced to the common). You have a common mode choke with 1000 Ohms resistance in parallel (to the common of the common mode). Now, why would the power choose the path of 10 to 40 times more resistance to invest its calories in?

I will be generous and pour 1.5KW into a balanced 50 Ohm load to develop 275V that is also across the 1000 Ohms of the BalUn. 76W into 50 beads. Now this verges on serious power for this load I will admit, but it also presumes key-down conditions which would only be found for RTTY or SSTV. By my bench measurements, I figure that the core's can tolerate as much power as the bulk equivalent carbon composition resistor - or least this is my rule of thumb. This means about 1 or 2W per bead to offer enough heat to cause pain, but perhaps not enough to blister. This is another benchmark from my days in the Navy.

I once asked an ET Chief how much heat a transistor could tolerate. He said
"If you can hold onto it and count to 10, it's not too much."

I've been blistered by TO-5 cans with just a casual brush and they still filled their design mission.

Your count is four terminals (not conductors), there are six. You need to come to terms with this shortfall in your count as it explains the utility and design of BalUns.

This "rate of change" is spurious, call it frequency dependant, but
then frequency dependency is neither here nor there at this moment.
More to the matter trying to turn this BalUn into a power transformer
is doomed in this analysis as it has absolutely no impact to
>correct
>most of the unbalanced to balanced coupling.

Source record: 62002

Below is a link to a comprehensive, 18-page paper delivered at the IEEE Broadcast Symposium last September with an extensive mathematical analysis and measured data from broadcast stations using CF antennas.

Some conclusions:

- A CF antenna is not quite as good in terms of gain and bandwidth as a reference monopole of the same electrical height.
- CF antenna performance increases as height and/or top loading increases, and for the same reasons it does so for a standard, short monopole.
- Given its performance, and the complexity of the installing/adjusting a CF antenna, a short monopole over a good ground plane could be a better choice.

Hohn Popelish wrote:
"I guess this depends on the official definition of "slow wave."

My dictionary of electronics defines "slow-wave circuit" as: "-A microwave circuit in which the phase velocity of the waves is considerably below the speed of light. Such waves are used in traveling-wave tubes."

William I. Orr wrote on page 6.11 of the 22nd edition of the "Radio Handbook":
"Spaced closely around the (TWT) beam is a circuit, in this case a helix of tightly wound wire, capable of propagating a slow wave. The r-f energy travels along the wire at the velocity of light but, because of the helical path, the energy propagates along the length of the tube at a considerably lower velocity than is determined primarily by the pitch of the helix." (I think Mr. Orr probably wrote: that is determined primarily by the pitch of the helix.)

I`ve seen several mentions of "slow wave" in the literature and it always meant slower than the speed of light. There is no need to limit the definition to microwaves as the coil slows the velocity across because the wave is guided by the wire wrapped around its form. The wire is longer than the coil form.

Best regards, Richard Harrison, KB5WZI

First, thanks for sending me those files. I have never been
able to generate a 4 TPI coil in EZNEC because of proximity
guidelines. How did you accomplish that?

Second, I thought EZNEC stored the design specifications
for the latest created coil and I was mistaken about that.
EZNEC must default to ten turns per foot.

However, the antenna is almost 12 feet tall, not the agreed
upon 8 feet. It would take a bigger coil to resonate an
8 foot antenna at 4 MHz. Bigger coil = more delay.

And I'm not encouraged by those numerous EZNEC guideline
violations. Download http://www.qsl.net/w5dxp/SUPRGAIN.EZ
for an omni-directional 20 dBi gain antenna that violates
the EZNEC guidelines. Incidentally, there seems to be a bug
in EZNEC. When I try to save the segmentation errors to a
file, EZNEC barfs and closes. I can't get a look at all
the errors so I don't know what they are.

I will continue to tweak the files, like adding enough coil
to bring an 8 foot antenna to resonance.

Yep. Type 75 operated at 10MHz is very lossy.

Thank you for some specific facts. I had no idea that you were using
a ferrite whose permeability falls to half the low frequency value
(about 5000 at 200kHz) at only 700kHz and is not recommended for flux
coupling applications higher than about 750kHz. It also has a very
low bulk resistivity of 300 ohm cm. At 3 MHz, its permeability is
only about 150 (and plunging).

Type 43 material has a permeability of about 500 at 3 MHz and falling
much more slowly.

If the cores don't have relative hi permeability (causing mutual
inductance in the two conductors passing through) they can't produce
any impedance in series with the common mode current. That is also
transformed over to the two conductors by mutual inductance (as a
loaded secondary reflected to those conductors as a primary).

If the radiator is perfectly balanced, the impedance of the ferrite
(transformed to the primary side) sees half of the voltage that is
between the center conductor and the shield. So if the coax carries
275 volts, half of that or about 1378 volts appears across the bead
bead common mode impedance. So a 1000 ohm common mode choke limits
the common mode current to 138/1000 = 138 mA. And if that impedance
is dominated by resistance, the beads will absorb 138*.138=19 watts.
50 beads will stand that indefinitely.

I don't think the O.P.'s balun has 50 beads, though.

It may not be the approach you are familiar with, but I think it is
valid. The transformer just has a lot of core loss, if you use a
ferrite optimized for a much lower frequency. And that loss shows up
as if it were a resistor connected across the ends of the two
windings. If a low loss ferrite (at the operating frequency) is used,
then the impedance across the windings is dominated by inductance, as
one normally expects with a transformer. But the analysis handles the
whole range of cases.

It seems that these references are not particularly concerned with the dimensions of the coil with respect to wavelength, or with the mode of propagation within the coil. I suspect that the term has different meanings to different specialties.

Your files contain multiple geometry proximity errors. Here is
what EZNEC says about your file:

http://www.qsl.net/w5dxp/ezerror.GIF

I started to print out the error file until I discovered it
is 142 pages long.

It seems to be impossible to model 4 MHz, 4 TPI coils in
EZNEC without multitudes of proximity errors. Proximity
errors result in gross errors in EZNEC results.

I'm sorry, Gene, but the results of your simulation cannot
be trusted.

I have a 70ft Rohn tower with a 15 ft mast. On the mast at +8ft above the tower head is a 9 element 2 meter beam, at +12 ft is a 5 element 20 meter beam (big) and at the top of the mast (+15 ft) is a discone. I have three sets of guys on this setup but they are not able to be set out as far from the base of the tower as is specified by Rohn because of the terrain. One set is only 18ft from the base of the tower.

We are in a very wind environment here in the Pacific NW. On the top of Scott Hill we often get wind storms in the winter with gusts to 70knots. This setup shelled out a Yaesu G-1000SDX rotor in one winter. This caused a free wheeling antenna that wound the coax around the tower like a vine on a tree.

Bottom line, the tower has been up for 5 years and there is no sign of trouble. This was used tower by the way. It had been installed in it's former application for 20 years.

Cecil,

As you know, generating the helix coils and using them are two separate things. I have only EZNEC version 3, which does not support automatic helix generation. However, there does not appear to be any reason why helices cannot be used in EZNEC version 3. That is what I did. I copied your wires, edited them, and re-input into EZNEC.

As for the height, you asked for an 8 foot whip. I adjusted my model until I got to a 10 foot whip. As I stated, I quit at that point. If you choose to further refine the model, be my guest. I doubt that you will find the magic wormhole into the parallel universe where everything is radically different.

Hi John,

Through these last comments, and those that go before, you have
entirely missed the boat of both the dynamics involved (this is not a
magnetic circuit being described, and there are NO magnetic lines
broken in a typical circuit in a balanced configuration), and the
topology. Specifically to this last, you still do not seem to
comprehend that a coax has three conductors and is a six terminal
device.

Roy has also commented to these issues and I think you should review
his correspondence and respond to him.

Cecil,

I did what you "challenged", with the exception of the exact whip length. (And the version I sent had a total height of 11 feet 9 inches, which is not absurdly unreasonable.)

I have to say I am surprised that it took you more than 24 hours to misinterpret what I sent (10 turns per foot) and then to blame the tools.

I don't see any of the errors on my computer.

There is little point of carrying this any further. You already stated that the results did not make technical sense to you and that perhaps EZNEC cannot be used for this task. I cannot repair your "technical sense", and I have no control over the capabilities of EZNEC.

Hi OM,

More is better? What do you seek to achieve that is not already
answered by Walt's article? Didn't he specify which type?

#64 material is going to offer about 3 Ohms per bead;
#43 material is going to offer about 8 Ohms per bead;
#73 & 77 material is going to offer about 18 Ohms per bead;
#75 material is going to show offer 28 Ohms per bead.

If you are running power into a matched load, you may want more of the
lower resistance beads. If you are running barefoot, fewer more
resistive beads will work.

Or you could do it the old-fashion way by looping your coax at the
drive point.

That probably explains everything. Version 4, with the helix
generation option, does a geometry check. The geometry of your
coil is unacceptable to Version 4 of EZNEC.

> As for the height, you asked for an 8 foot whip. I adjusted my model

Actually, you stopped at 11.775 ft., ~12 feet as I stated earlier.
It won't do any good to keep going. The coil you generated is
unacceptable to EZNEC 4.0.

But thanks for your effort. I learned something about EZNEC.

Broadband transformers, which can operate well over several decades of frequency, commonly use ferrite cores which are essentially resistive over most of the operating frequency range. The sign of the impedance is unimportant to the transformer's operation; all that's necessary is that its magnitude be adequately high over the operating range (and of course that the core's permeability be adequately high). The wide band high impedance requirement is virtually impossible to meet with an inductive core whose impedance is approximately proportional to frequency, but easily done with cores whose impedance is essentially resistive.

Hi OM,

Think of the beads as series 1W resistors. Ask yourself how much of a common mode load they will present to the antenna "as a source" (this means that the dipole will look like a KW source with complex impedance).

You then have to judge the potential that source will present in Common Mode to the beads. Elsewhere in this thread I've done a simplified analysis that suggests 50 #75 beads will get a tad hot under matched conditions because they are dissipating roughly 1.5W each. "Hot" is of little consequence until we shatter the ceramic because of thermal stress (the sintered product contains bulk irregularities). That stress could be arguably applied through a rain drop hitting a bead. Then we get into new issues of balance and symmetry because one part of the bead is cooler than the other. ;-)

If, instead for this matched load, you replace the 50 #75 beads with 80 #73 or #77 beads; then you have roughly the same total resistance, but the heat dissipation (still 1W suggested load for each) is spread out more. Again, moving off resonance demands another analysis.

I appreciate you taking the time and effort to try to straighten me
out on this, but if there is no magnetic lines broken (whatever that
means) why use a magnetic core? Why wouldn't disks of carbon work
just as well. They are certainly resistive.

But resistive impedance isn't the only characteristic of ferrite. Disks of carbon won't work because they have a relative permeability of one.

Fair-Rite type 73 ferrite has a Q of 1 (R = X) at about 3 MHz, and is essentially resistive above that; it's a "low frequency" ferrite. But its relative permeability is 700 at 10 MHz and 70 at 100 MHz. (Note that the permeability is a complex quantity, and that the permeability is mostly imaginary, hence the impedance resistive, at the higher frequencies.) Carbon has a relative permeability of one at all frequencies. The impedance of a type 73 ferrite core picked at random from the Fair-Rite data shows an impedance of 23 ohms at 3 MHz, 37 at 10, 51 at 100, and 49 at 200 MHz. Try making a carbon disk that'll give you that impedance. And if you make your baluns with multiple turns on a single core as I do, you'll have much poorer coupling between turns on a carbon core, than on ferrite.

You'll learn a lot by reading the information in the Fair-Rite catalog, available at their web site. Good, professionally written information on EMI suppression is useful also. But I don't recommend looking to amateur publications and web sites for information on ferrites -- too many people share the same misconceptions you do, and pass them along without really understanding how transformers work and the properties of ferrites. Actually, a large number of engineers share those misconceptions, too. It's often one of the first things I have to explain to the engineers in my consulting work.

Hi John,

Breaking magnetic lines (flux) is a commonplace of fields, motors, and generators. A single wire that passes through a bead, torus, or core will build a magnetic field concentrated within that structure when the circuit is completed outside of it. The flux lines of half the loop will penetrate the core to reach the other half of the loop. The core breaks the magnetic line of flux. The dissymmetry of penetration builds a magnetic field in the core.

However, when the complete current loop is within the same structure, the flux lines do not fulfill that same function. The flux lines that do emerge from the tightly bound wires can be said to penetrate the torus, but here the symmetry creates bucking fields, the net effect is as though there was no core at all (except to add capacitance).

Both models attempt to stimulate a current within the toroid, the common mode of the single wire model above is lossy, the differential mode of the twin line model that followed sees nothing. Superpose these two for the coaxial solution.

To put this to a test. Load up your rig, through a SWR meter to a dummy load using two short connection wires (this will undoubtedly require adapters and such to break out both paths). You should note a 1:1 indication. Place two #75 beads on ONE wire. You should note a 2:1 indication. You have just inserted 40 to 60 Ohms of additional resistance into the circuit. Now, move the same two beads to encompass BOTH wires. This should return the SWR meter to a 1:1 indication.

If you are going to have to go out and buy the cores, type 43 (and its competitors) is way more common and cheap than any of the others. It is also readily available in long form toroids called shield beads.

For instance, Digikey sells the Steward version of type 43 (called type 28) beads part number 28B1122-100, with a 13.7mm hole and 28.6mm long. This part produces about 60 ohms per bead at 4 MHz and costs $20 for 10 pieces.
http://www.steward.com/

What diameter coax do you want to use a choke BaLun on? Generally the smaller hole size, the more impedance you get out of a given length core.

As long as the impedance is high enough, what is the need for it to be
constant (or even nearly so) over a useful frequency range?

If magnetic lines can be broken, doesn't that imply
the existence of magnetic monopoles which have never
been found to exist in reality? :-)

> builds a magnetic field in the core.

I cannot picture what you are saying. I guess I need a picture. The
way I understand flux, is that, any current has flux wrapped around
it. Putting a core material around the current allows the flux to
increase in magnitude in proportion to the permeability of the material.

> However, when the complete current loop is within the same structure,
> the flux lines do not fulfill that same function.

The simplest way to say that is that two equal currents going in
opposite directions have magnetic fields that cancel well outside the
pair of conductors. It doesn't make a lot of difference if the two
currents are coaxial or side by side, as long as the flux path
surrounds both of them.

> The flux lines that
> do emerge from the tightly bound wires can be said to penetrate the
> torus, but here the symmetry creates bucking fields, the net effect is
> as though there was no core at all (except to add capacitance).

Since the magnetic fields from the two currents cancel (at sufficient
distance), there is no flux to enter a surrounding core. The only way
bucking takes place is if the two currents are side by side. Then
there is some flux leakage near the two current paths, but the fields
these create buck each other in the two halves of the core, so there
is only local flux fringing into and back out of the core.

> Both models attempt to stimulate a current within the toroid, the
> common mode of the single wire model above is lossy, the differential

As I understand common mode current, it is the net imbalance between
the current through the center conductor and the current through the
shield.

Yes, obvious to the casual observer. You can string beads all along a coax, and if it had no common mode current in it, this will make absolutely no difference in how the coax acts.

OK. I gave an example of a traveling wave tube which uses a coil specifically to retard wave progress ao that an electron beam could keep up with a signal winding its way through the coil.Terman describes the Traveling Wave Tube (TWT) starting on page 678 of his 1955 edition of "Electronic and Radio Engineering".

Here is another version of how the TWT works. The TWT was developed to provide wideband gain, about 10 to 60 dB over 10% of the operating frequency or more, and produce a power output of one kilowatt, if needed.

The TWT consists of an electron gun similar to those used in CRTs, a wire helix, and a collector. The gun at one end of the helix produces a focused beam of electrons directed through the center of the helix. The helix is a uniform coil of wire used to slow down the forward progress of an RF signal fed into the gun-end of the helix inside a glass vacuum tube. Output is taken from the helix at the collector end of the helix. The collector and the helix are positively charged. The collector is the electrode which catches the spent electrons which have traveled through the length of the tube.

A magnetic field distributed along the length of the TWT is used to keep rhe electron beam from spreading during flight.

Transfer of power from the direct current of the electron beam to the RF signal is by velocity modulation of the beam into periodic bunches of electrons. these accelerating electron bunches generate a stronger signal along its path. Interaction between the electron beam and the helix is continuous and accumulative. Amplitude of the signal grows as it travels down the helix.

The axial wave velocity is fixed by the helix while the initial eleectron velocity (before modulation) is proportional to the positive potential on the helix and collector.

The signal to be amplified is fed to the end of the helix nearer the electron gun. This RF signal travels as a surface wave around the turns of the helix, toward the collector, at about the velocity of light. The forward or axial movement of the signal is slower, of course, because of the pitch and diameter of the helix. This forward movement of the wave is analogous to the travel of a finely threaded screw where many turns

are required to drive it into position. The signal wave generates an axial electric field which travels with it along the longitudinal axis of the helix. This velocity modulates (slows down and speeds up) the electrons of the beam current.

So, the wave traveling from one end of the coil towards the other is a "slow-wave" while the wave travelimg around the coil turns is only slightly slowed below the speed of light. This is how a coil works. Frequency and coil form matter but don`t change the basics.

Best regards, Richard Harrison, KB5WZI

You are going to get into trouble with the W2DU balun at high power levels or with high commonn mode voltages across the balun. Each bead suggested is only good for about 1/2 watt dissipation in open air during long duty cycle.

Also, a string of beads is a terribly inefficient use of ferrite materials. If you double the expense of the balun by doubling the number of beads, you only double the common mode impedance.

If you use a less resistive material with lower loss tangent and multiple turns through the core, you can greatly increase power capacity and choking impedance with much less increase in cost.

73 or 75 material beads are great in 50 ohm systems at modest power on higher frequencies when the common mode excitation is low, but I'd stay away from that method at kilowatt power levels especially if common mode exciting the shield is high in level or frequency is low.

For high stress applications a string of beads is terribly inefficient.

Cecil,

I have no idea what you did, but you screwed something up quite royally. There is no way that segment 3 is too close to segment 197.

I just ran a cut-down version in the EZNEC 4 demo, and I found no geometry errors. Yes, each segment length is too short, about 80% of the recommendation, but Roy indicated a couple of days ago that should not present a big problem. I cannot say much more about EZNEC, except that I did not see any problems.

The coil I modeled is very similar to the Texas Bugcatcher model 680 coil. (http://www.texasbugcatcher.com)

I don't own a Texas Bugcatcher coil, but I suspect they actually work more or less as advertised.

I assume you are talking about the beads mentioned in this document:
http://www.w2du.com/r2ch21.pdf

At the bottom of page 21-6, he says that the beads have a .197 inch
hole and are .190 inch long.

The beads I am suggesting are over an inch in diameter and over an
inch long. A half watt would barely raise their temperature
noticeably above ambient. And they will fit over coax that is a half
inch in diameter. There are other shapes that are more cost effective
for smaller diameter coax. 28B0591-200 has a .23 inch hole, but is
1.38 inches long, with a .591 inch OD. A half watt won't warm that
one very much, either. And it costs only $.76 each, if you buy 10 of
them.

My point was that there are cheap long form factor toroids available
now, that weren't available when W2DU designed and described his BalUn.

> Also, a string of beads is a terribly inefficient use of ferrite
> materials. If you double the expense of the balun by doubling the
> number of beads, you only double the common mode impedance.

But it spreads the heat out, and doesn't require you to kink the coax,
which makes it last longer in the weather. If you want to wind large
diameter toroids, they now make low cost versions of these for EMI
purposes, also. For example Steward # 28B2400-000, outside diameter
2.4 inches OD, 1.4 inch ID, .5 inch thick costs only $3.36 at Digikey,

quantity 1. Again, Steward type 28 is roughly similar to Fair-Rite type 43.

> If you use a less resistive material with lower loss tangent and
> multiple turns through the core, you can greatly increase power
> capacity and choking impedance with much less increase in cost.

Yes, the turns squared effect makes better use of the mass of the ferrite to produce impedance.

The choke impedance is inductive at low frequencies. Loss in the ferrite material is low.

But due to a lossy ferrite material at the higher frequencies the equivalent circuit is the inductance in parallel with a high resistance.

At sufficiently high frequencies the choke impedance is almost a pure high resistance. Which chokes the current just as well as a high inductive reactance.

This is all that's necessary to explain the operation of a choke balun.

I can't imagine why you are all making such a fuss about it.

Reg.

I wind about 10 turns of RG-174 type coax on a core having an OD of a bit more than an inch. Works fine up to at least 300 watts with a reasonably matched antenna.

Sure.

The problem actually all comes down to the common mode current flowing through the beads, and that's the same as looking at voltage across the shield from one end to the other of the "choke".

Some antennas, even with very low power and 50 ohm feedpoints, will produce fairly high across the string of beads. This can cause quite a bit of heating, and cause the feedline to remain part of the radiating system despite the use of a balun.

In controlled situations strings of beads work pretty well. In other cases they are totally inadequate, and the problem can have nothing to do with the impedance across the feedline (SWR).

I never use strings of beads on my antennas.

My point is dollar for dollar multiple turns always wind up being a
better investment. That's because impedance approximately follows the
square of the passes through the core.

I've never once had cable fail from being wound on cores. I can't
imagine why someone would need to kink the cable.

The only part of the cable that significantly increases CM impedance is
the part inside the core window. Why care how tightly the cable is
pulled against the core outside??

At low frequency, I understand how this is a good approach (though
this discussion was about the W2DU style choke balun). But at higher
frequencies, I am concerned that the turn to turn capacitance might
provide a low impedance path that parallels the choke. A string of
beads does not have this problem.

I always try to not bend any cable to a smaller radius than the
manufacturer recommends, and I am not familiar with this
recommendation for common coax types used by amateurs. I would have
to look that up before wrapping a core.

> The only part of the cable that significantly increases CM impedance is

The weight of the cable will tighten the turns on the core.

I just found this rule of thumb that says coax should not be bent to a
radius smaller than 6 times the cable diameter.
http://www.wiremold.com/www/commercial/education/white_papers/index.asp?wpid=4

For RG-58 this comes out to about a 1.2 inch bend radius.

This spec for RG 58:
http://www.pacificcable.com/Picture_Page.asp?DataName=RG58
Specifies 1.25 inch minimum bend radius, only if there is no pull on
the cable. If the cable is tension loaded, they recommend it be
wrapped over a minimum 2.5 inch radius form.

That would get to be a pretty big coil on a toroid.

I have never read nor heard of that explanation of the Hindenberg disaster. Certainly diesel fuel may have been involved, but the huge ball of fire has, in everything I've ever read, been attributed to hydrogen. Hydrogen IS explosive and therefore dangerous. For that matter, so is pure oxygen as we learned in early Apollo days.

Do you have a reference for the attribution of diesel fuel as the sole cause of the Hindenberg disaster? I'd love to read it.

Thanks

John

Hi John

"For what its worth", I have wounf the coax around a single ferrite toroid
with the exact amount of turns and spacing so the impedance along the
conductor of the coax outer shield was maximum, as in parallel resonance.
I cant claim that it does any better job than any other "1:1 balun", but it
worked for me.
My point is - The turn to turn "stray" capacitance doesnt necessarily have
to be a source of performance degradation.

Jerry

Some time in the past I read that one source of the brilliant fast moving
flame evident in
the old newsreels of the Hindenberg disaster was the doped fabric skin of
that dirigible.
It was said that it might as well have been celluloid, a near relation to
guncotton. I was only 4 at the time so can claim no direct knowledge beyond
my reading about it.

I think of it as more of a upper limit. Once you are above resonance,
the choke action has to drop. And if you are using one of the low
frequency ferrites, the resonance isn't going to be anything to write
home about either. ;-)

Cecil,

I forgot to say one thing.

It appears that the files I sent you got corrupted somehow. First there was the problem of "10 turns per foot" and now all the geometry check errors. (Did you drop the card deck on the floor?) 8-) 8-)

The original files are still good at my end. I will resend if that will help.

There was a very interesting documentary on public TV a few years ago about that -- it might have been Nova. Their conclusion was that the combustion was started on and supported by the fabric's paint, which was loaded with rust and aluminum powder -- thermite! (See for example http://en.wikipedia.org/wiki/Thermite.) Samples of the painted fabric kept by some witnesses proved to be extremely flammable.

Hydrogen is explosive only in the correct, fairly narrow, range of mixtures with oxygen. A big bag of hydrogen won't explode. It'll burn only at the outside edges where it's mixing with oxygen. It'll rapidly disperse to a point where it's too lean a mixture to burn, so I believe there's only a fairly narrow physical region around a blob of pure hydrogen where it's flammable. Hydrogen stopped being used for dirigibles more because of the danger perceived by the public after seeing the Hindenburg than by real danger.

Hi John

I am not smart enough to be able to give instructions to *anyone*. But, I
have thought of "hi Q" resonance something I want to avoid anyway in making
a Balun. I was worried that a high Q resonant circuit without sisnificant
loss might assist coupling to the feed line if/when that feed line was close
to some multiple of a half wave.

Anyway, you get the idea I was trying to address concerning any worry about stray capacitance ruining the Balun performance.

Jerry

You only get the geometry warning after the creation of the
helix, not after you store and reload the file. Create the
helix and you will get those geometry warnings.

Gene, you won't understand what the problem is until you create
the coil in EZNEC 4.0. Right after creation of the coil, EZNEC
will display the geometry errors. After that, the geometrical
errors appear to be down the list from the segment errors and
unavailable for viewing.

Not a valid point.

Say we have 1000 ohms XL in parallel with 1000 ohms Xc at 10MHz. At 14 MHz we have 1400 ohms XL in parallel with 714 ohms Xc. The combined reactance is just over 1400 ohms.

Capacitive reactance in parallel with inductive reactance increases the impedance, until we are over 1.414 times the resonant frequency. Anyplace below that, the shut C decrases unwanted coupling.

If you look at actual chokes, you'll see that is a totally unfounded concern at HF.

That toroid showing the flipped winding that is supposed to reduce stray C? It actually makes a choke work slightly worse...not bettter...until we get way up in VHF or UHF.

> I always try to not bend any cable to a smaller radius than the

Manufacturers are very conservative. I use RG400 in very tight coils without any issue, and my main baluns are all air core RG213, LMR400, or RG8X. I do some very tight radius bends without problems. My 160 vertical array uses a phase inverting transformer made with RG-400, and it is two parallel 3" tall stacks of 61 material 2" OD cores wound as tight as possible with RG-303. It handles huge voltage across the winding without any issues.

Simple to fix. Don't hang anything from the cable leaving the core.

I have over 300 feet of RG8X hanging vertically from a high dipole, but I have a rope lacing the cable as a strain relief. Been up since 1999.

All sounds good to me. I just hadn't computed the turn to turn
capacitance for wound coax shield to figure out how high you would
have to go in frequency before the capacitance would be a limit. Glad
to hear that there is lots of range where it is no problem.

Most of the black smoke and flame you see in the newsreel footage is
from the fuel supply and the painted canvas covering of the zeppelin.
Hydrogen when it burns is not visible and since hydrogen rises it
quickly dissipated upwards.

Well, google finds this one easily

http://www.hydrogennow.org/Facts/Safety-1.htm

and this one that puts the blame on the coating on the envelope

http://www.abc.net.au/science/k2/moments/s1052864.htm

and another

http://www.ch2bc.org/hindenburg.htm

All were from the top 10 that google found, you can do it as well. I
searched for "hydrogen hindenburg".

There are lots of sites that deal with the history, and none of them
that I have found place any of the blame for the deaths on hydrogen
combustion. Except perhaps for the ignition. And that part will never
be known.

I've been wondering why you could create close spaced coils
and I couldn't without objections from EZNEC.

I've been sitting here creating coils to see where the geometry
check fails. On 4 MHz, with a 25 turn coil and a 0.5 ft. diameter,
the turn spacing passes the geometry test at 0.175 ft. and higher
but fails at 0.174 ft. and lower.

It just occurred to me that this geometry check failure that I have
been seeing might be a bug in EZNEC. I just downloaded and installed
the latest update and the problem seems to have been resolved.

I apologize for any confusion.

It just took from post number 808 to post number 840, about 30 posts, to resolve an error occuring in one person's computer. For a real treat, go back to post 808 and start reading the tone of the entire exchange, and make a written list of the errors.

Imagine how long it would take to resolve something complicated in this thread!

Now you see why I won't get into this. I go to Waffle house when I want to look at someone turning out waffles at a high rate of speed.

3813. Adjusting a colinear antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-30 15:09:01 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <kwSWf.6462$bX5.759@dukeread04>
Source record: 62074

I'm building a 4 segment + whip coaxial collinear antenna for
2.441 ghz. The coax I'm using is RG58 with a VF of .66 but
I was told by some of you that the VF will vary on this antenna.

What I need to know is which way and how much should I
adjust the element lengths to compensate?

Also, I followed the instructions on this webpage to the letter:

http://wireless.gumph.org/content/4/3/011-mini-wireless-antenna.html

But instead of getting sector lengths of 40.5mm, I got 39mm
somehow. Have I created a waste of time because of that?

One last question - with HF antennas, if they are close to other
objects they sometimes need to be shortened slightly to work.
I plan on mounting these antennas on the back of my ThinkPad's
display so maybe they will work being 1.5mm short per sector?

God I love this stuff!

They're just disembodied statements, Cecil. Come back
when you can supplement them with some theory and
experimental proof.

It is trivial to use EZNEC to stick a coil at those points.
I have offered EZNEC proof on my web site. Nobody
wants to discuss it. Wonder why?

When I was at Intel we didn't blame our customers for Intel's
programming bugs and software problems.

I am happy to find out that my years-long struggles to create a
decent coil in EZNEC was a program bug. Thanks to you, EZNEC
is twice as useful to me today as it was yesterday.

Reg, if the SWR on a piece of transmission line is infinite and one tries
to use the standing wave current phase to measure the propagation
delay in a piece of that transmission line, what would be the result?

Source record: 62080

Hello all,

I am new to the group but have a specific reason for joining. The primary reason I joined, like many of you I am sure, is to get information about short wave radio. My situation: I have the appropriate parcel of land (110) acres that is free from any legal impediments to building a short wave radio tower. The land is located in West Central Alabama, in rural Fayette County.I also have the necessary funding to build a short wave radio tower and transmitter. The site has been evaluated as a perfect location that is virtually free from any potential liability and from the perspective of reaching millions of people in Mexico and Central America.

Questions for the group:

1. What are the potential financial rewards for owning and operating a short wave radio transmitter/tower?

2. How does an owner go about establishing a revenue stream from potential purchasers of air time.

3. Who would the primary customer base be?

Comments or suggestions?

Thank you,

DrJoe (newbie)

Well, this is a radio _amateur_ group, but there may be some pros
lurking around. Here are some uninformed opinions to keep you going,
however:

1. One of the best quotes I ever heard about hobby businesses was "the
way to make a small fortune in model airplane motors is to start out
with a large one". I don't know if that applies here. Potentially I

expect that a single transmitter/tower would net you no more than a decent full-time job as a station manager. It would only buy the fleet of BMWs if it was the seed for a great many more.

2. Identify potential advertisers and sell air time. I have _no idea_ of how that works in shortwave, but I imagine you'd be traveling in South America a lot.

3. People who sell stuff to the shortwave listening public.

Questions to ask are:

* What are the regulations surrounding what you're trying to do, both in the US and in any countries you may wish to travel to and remain unarrested.

* What effective radiated power will you be allowed, and what's the most cost effective antenna/transmitter combination to get you there?

* If you plan on starting small but want to upgrade later is it best to start with a dinky antenna and big transmitter, big antenna and dinky transmitter, medium-dinky on both?

* Who would listen to this stuff?

* What do they buy?

* Who sells advertising for that stuff?

* Do they believe that advertising on short wave would work?

* Will they believe that advertising on _your_ station would work?

* How can you contact them?

* Can you work out the financial details cross-border so that you won't get cheated, and your customers won't have to worry either?

Hey Tim,

Thank you very much for the information. I really am just starting to investigate the possibilities. My interest was peaked when I received an offer to buy the land I own for approximately 3 times the approased value from a man in NC who owns and operates these types of facilities. His particular bent, like many these days I am sure, is religious broadcasting, but he disclosed in our conversation that this group of potential advertisers/sponsers would more than pay for it. After our initial conversations, I just decided to check out the possibilities before I went and did anything like actually sell him the land.

Joe

Let me ask it a little differently. We all know what a plot of the standing wave current magnitude looks like up and down an open-circuit transmission line.

But what does a plot of the associated standing wave current *phase* look like up and down that same open-circuited transmission line?

Hi Joe

You probably realise but thought I'd mention that this newsgroup is more oriented towards "amateur" or "ham" radio non commercial systems. The rules/laws for operating amateur equipment are a lot "looser" than those for a commercial enterprise you are suggesting. The license cost is also far lower than what you are looking at.

I would suggest that shortwave broadcasting probably isnt going to do very well as a business enterprise given the set of technologies that are around now and coming soon. Satellite based systems and broadband networks are probably a more likely source. I realise that you mentioned that your market is more south of here but satellite radios (for example) will eventually be as cheap as shortwave radios and have much better audio quality. Given the capital investment you are thinking of I would think you wouldnt have enough time to realise a good return.

I might also suggest that the nature of shortwave propogation is that it isnt as reliable as you'd like. Stations like VOA handle this by using a number of different frequencies depending on conditions at the time. This obviously increases the $ investment in equipment/antennas and concerns over listener education (where to tune) may mean a loss of market.

re question 1;

You cant setup a system whereby the listener pays for receiving so your income stream is going to be more advertisers or others that might use the station for their own purposes. What does the Mexican, South American market want? I'll admit that this is somewhat beyond my experience.

I should point out that this topic isnt in my normal purvue. I hope however you find my comments useful.

Cheers Bob W5/VK2YQA East Texas.

Tom, W8JI wrote:
"Many people vizualize current in a small loading inductor as starting at one end and traveling through the conductor turn-by-turn.

That`s how the experts say the coul in a TWT works, and it is no different from other coils.

RF energy travels in waves which induce currents on conductors in their paths which in turn induce more waves.

Energy has no choice but to follow the conductor. It is nonsense to say this is not the means used by energy traveling through an inductor while riding on its surface due to skin effect. The energy follows the conductor wrapping its way around the form fron start to finish.

Energy hits the speed limit of physics if it can at 300,000,000 meters per second. but
its interaction with any conductor slows it depending on the characteristics of the conductor guiding it.

An inductor reduces the group velocity (actual energy velocity) of any wave traveling along its surface. The group velocity is always less than the velocity of light (300,000,000 m/sec.). Phase velocity may exceed the velocity of light but only to the extent that the actual group velocity is slower than the velocity of light.

An inductor reduces the group velocity of a wave traveling upn is surface.Inductors are also known as "retardation coils".

The RF`s changing current generates waves. In an inductor, it ideally lags voltage across that inductor (as a circuiy element) by 90-degrees. Time represented by a 90-degree delay can be calculated by: velocity = frequency x wavelength. 90-degrees is 1/4-wavelength.

It is possible to measure the delay of a circuit but when your measurement seems to violate the laws of physics it`s more likely your measurement was flawed than you have discovered any new physics.

Tight coupling does not speed transfer of energy through a coil. TWT coils are tightly coupled. Remember, the coil does not allow current to change instantly. Lenz`s law prevails. Current lag enforces a delay.

Tom also wrote on "Welcome to W8JI.com":
"An inductor delays the flow of current in relationship to applied voltages as the magnetic field inside the coil expands. Voltage increases before current starts to flow. This phase relationship berween voltage and current is often confused with time delay in the inductor."

I`m done with my critique only because I`m out of time.

Best regards, Richard Harrison, KB5WZI

Commercial Radio License = $$$$$$$$$$$$$$$$$$$$$$$$

It takes a long time to recover your initial investment.

Look into planting something with less capital investment and a higher
rate of return.

As stated in another response, this is amateur, meaning NOT FOR PROFIT'
radio. I have $12000 invested in my station with absolutely NO rate of
return in $$$ terms.

Measure the velocity factor (at or near the operating frequency)! If you are using solid polyethylene dielectric cable, then the v.f. really should be close to 0.66. For a flat pattern, you want the center-to-center spacing of the elements to be 1/2 wave, considering the net velocity factor. I say net because at the junctions between elements, it's possible that the effective v.f. is slightly higher than in the coax itself. You'd cut the elements long by enough to let you solder them together and end up with that 1/2 wave center to center. (It's easier and equivalent to measure from top of one element to the top of the next element, etc.)

Since the _pattern_ depends mainly on the phasing of the feed system, and the phasing is established mainly by the propagation velocity in the line, and not by the surrounding environment, putting it next to something won't affect the pattern, except that if there are conductors in that display you want to mount it to, they may very well screw up the pattern by allowing current where you don't want it. Especially if there is some piece that's resonant near the operating frequency it would be like putting an unwanted parasitic element in a Yagi: not a good idea for optimum performance.

OK, so the phasing is designed to get you the right pattern. But the phasing is independent of the feedpoint impedance. You need to match to that, and you also need to decouple the antenna from nearby conductors. Any conductors in the display fall into that category, but the feedline from the xcvr also does. A choke balun, and other feedline choking, is very highly recommended.

I used to have a web page with quite a bit of text about the why and the how of coaxial collinears; it wasn't a construction article, but it armed you with enough info that you could go out and make one that would work well on pretty much any frequency you might want. It included things like why the center-center half wave spacing, and why it's slightly better to use foam dielectric cable. If I got enough requests, I'd make a revised version of that available, maybe even with some pictures this time. Every once in a while I get a request to re-print it in a club newsletter, so I know there are some of those floating around out there.

Cheers,
Tom

Indeed. And I even gave the answer some time ago -- the phase of the total current (which Cecil seems to like calling the "standing wave" current) is the same all along the line. That's true only for the case of a line that's completely short or open circuited. In any other case, the phase of total voltage and current vary along the line. This can be easily calculated by adding the values of the forward and reverse traveling waves at each point to get the total at each point. Or, if you're lazy, just plug the numbers into the equations you'll find in _Reference Data for Radio Engineers_ or your favorite reference. Or if you're lazier yet you can model a transmission line with EZNEC or the modeling program of your choice and let it tell you what the phase of the current is at each point along the line. Any of the three methods will give the same result if done correctly.

As I mentioned before, a plucked guitar string is a good physical analogy. Each point along the string moves in the same direction at the same time, showing that the motions at all points along the string are in phase.

That's very basic transmission line theory. If Cecil really doesn't know the answer to the question he asked, it's no wonder he has such

conceptual problems with inductors and transmission lines.

> different from other coils.

That's not correct at all Richard. The coil in a TWT tube behaves considerably different than a small inductor operted at a low frequency.

Nearly everyone on this thread seems to understand mutal coupling is very high in a conventional loading inductor. This is why the inductor comes close to following a square of the turns change in inductance. A TWT has a loose coil operated in an entitrely different mode, behaving much more like a axial mode helice than an inductor.

It can easily be proven inductors don't behave the same way when they have wide turns spacing and long form factor and low values of distributed capacitive reactance to the outhside world...when compared to an inductor who's displacement current is very low compared to through current.

Coils or inductors can range from having very low phase difference between each terminal (almost immeasureable) to very high values (a helical antenna or tesla coil at resonance).

The only real argument against this seems to be from Cecil, and as I understood it he thinks standing waves are what causes current to be different at each end and somehow sets the phase difference between ends of the inductor.

I can have a fixed style of antenna on a fixed frequency, change only the inductor design, and go from something that almost perfectly behaves like a lumped component to something that has noticable current taper across the component.

Most people had this stuff right from about post one.

I rarely see a thread go nowhere like this one has. It reminds me of the Fractal antenna threads years ago, or that silly conjugate match stuff that went on for years and years.

800 posts later the same major group of people seem to agree, the same one or two people seem to think something magical occurs in an antenna making a regular lumped inductor behave like a self-resonant helice

with standing waves and all.

It's sure a time waster.

But Roy, you measured the phase of the standing wave current to try to convince us there was no phase shift through a loading coil. You cannot have it both ways. You cannot use the phase of the standing wave current to measure a phase shift through a loading coil and then tell us the phase of the standing wave current is the same all along the line. So which story are you going to chose?

I suspect that when you made those measurements, you didn't realize that standing wave antennas have standing wave currents and that the currents reported by EZNEC for standing wave antennas are standing wave currents with unchanging phase.

If the phase of the standing wave current cannot be used to measure the delay through a wire, what made you think it could be used to measure the delay through a loading coil?

> sections won't have the correct phasing.

If I sounded like I was saying it was a "good" antenna I'll clarify.

As I haven't actually measured any, I may be talking out of you-know-where,
but will anyway...

To pick at a point.
I believe the phasing comes out correct. That is, you should be able to
get 180 degrees change in the coax sections. However, because the resulting
outside radiating element is shorter than a half wave (and they are touching
end-to-end), the element spacing is closer that you get with even full half
waves stacked end-to-end and therefore the lobe compression will be less.

Also, as the phase departs from 180, due to measurement errors, you get
further degradation and then the coax loss means unequal power in the
elements, so things go down hill fast. I would suspect that simply putting
a 1/4 antenna outside the box would give same-or-better performance --- and
save the possiblilty of cutting up your fingers with the Exacto.

In spite of the bad science, with RF being RF, it *could* work out that
just having some lesser power extricating itself from the upper quarter wave
element may provide the poor bloke with improved reception. What do they
have inside the computers or cards anyway? --- it most likely isn't a clean,
in the open, well defined antenna, but some compromise design. Good enough
is always good enough even if good enough *is* 20 dB down.
Another source of false science is the location/orientation of this
antenna and the one it is talking to. This construction (assuming he mounts
it upright the way we might think) is assuming that the WiFi antenns is
horizontally in line with his and the polarization where he is, is vertical.
You have an RF sea to swim in.

A 75m bugcatcher coil is not a small inductor. You guys have
backed so far out of the basic real world argument that we can't
even see your coils anymore without a microscope. Of course,
microscopic coils have delays that can be ignored. 75m bugcatcher
coils are not microscopic. They are HUGE!

How you can argue that the magnitude of the current is the same
at both ends of the coil when 12 out of 13 of the measurements
showed they were different is magical thinking, divorced from
reality.

> The only real argument against this seems to be from Cecil, and as I

If you don't understand that fact of physics, you don't understand
the distributed network model at all. In a standing wave antenna,
there exist forward current and reflected current. Any model that
doesn't take that fact into account is doomed to failure.

> 800 posts later the same major group of people seem to agree, the same

The magic is that current travels through coils faster than the speed
of light. That's what your lumped-circuit argument presupposes. It
also completely ignores reflected waves.

Doesn't it seem logical to use a model that includes reflected waves
when one installs a loading coil in a standing wave antenna?

>
I know that a few SW BC stations make money from commercial sales,
however, the majority are non-profit organizations or government run
stations without a means of making income.

>
>3. Who would the primary customer base be?
>
>
You have to determine your market. If you are broadcasting to Mexico,
you will have to find someone wanting to market to them. A few
stations are broadcasting to US markets part time for commercial
revenue and also to foreign countries. SWBC requires the majority of
your content to be directed at the foreign listeners.

>Comments or suggestions?
>
>
The cost of setting up and getting approval of a SWBC station will
very likely exceed $1 million. I believe minimum power is 50 KW, which
requires electricity at premium pricing. Transmitter specifications
are strict and, if I was correctly informed, since your station is
international, it will require you have on board when it is

transmitting, a General RadioTelephone licensed engineer.

>Thank you,
>

You are welcome.
>
>DrJoe (newbie)

I once dreamed of owning my own SWBC station. Every time I
investigate the requirements, I find my dream is more like a
nightmare.

Wishing you the best,

Cecil,

I guess I am a bit puzzled.

The bugcatcher example I sent you showed a phase shift of about 7 degrees at 4 MHz. The current at the top of the coil drops off to about 85% of the base current. I believe the delay computes to something around 5 ns. That does not seem like a HUGE delay for a coil that contains nearly 40 feet of wire.

I presume you can now duplicate and verify these results, since we have not heard any contrary information. That coil is real close in design to a genuine Texas Bugcatcher #680 from Henry Allen.

Absolutely no one around RRAA clings to a rigid lumped component model, except your straw man. The distinction is that most people treat this non-ideality as a perturbation. You seem to want to elevate it to the status of realignment of the planets.

It has been explained over and over why real coils are not ideal. I am sure you understand. I am not at all sure why you persist in carrying on this rather pointless argument.

I've been waiting for you to come back with the facts that
contradict W8JI's measurements. Thanks once again.

The coil has about half the inductance of the 100 uH coil
measured by W8JI. He measured ~4 degrees in 100 uH. EZNEC
reports 8 degrees in 60 uH for an 8.5 foot antenna.

My wild ass guess was at least five times more accurate
than W8JI's measurements. Thanks for pointing that out.

No one is going to purchase advertising time on your station unless
you have programming that appeals to the people that the ads are aimed
at.

Programming that appeals to people in the 25 to 54 age group pulls in
the folks who have the most money to spend, and it is to them that you
might want to aim your programming.

And what would that programming be?

And do you have the money to finance it?

As an amateur, I'm not offering any commercial advice here, just
posing things you may not have thought of.

A transmitter and shortwave tower is only, to paraphrase Ed Murrow,
just a box with wires and stuff in it...

Cecil,

I did not say anything about W8JI's measurements. He had a completely different setup, and I had nothing to do with it.

You have a remarkable Teflon coating. I completely called your bluff on the bugcatcher coil, and you simply ignore the result and slide away to some other Don Quixote adventure. I am not really surprised, of course.

Dr. Joe,

Your questions are quite off-topic for a newsgroup dedicated
to Amateur Radio antennas. Perhaps you should seek the expertise of
some commercial radio professionals in your area...

> . . .

I maintain that there's no such group as "other coils", but that coils act quite differently depending on their physical sizes and the amount of coupling between turns.

I believe that current traveling down a straight wire goes at nearly the speed of light. I also believe that if you take that straight wire and wind it into a helix with very widely spaced turns, it also travels down the wire at nearly the speed of light. But if you wind a helix that's short in terms of wavelength and with a reasonable length/diameter ratio, the field from the current in each turn couples to all other turns, which makes the propagation axially from one end to the other close to the speed of light. That is, for the same length of wire, an inductor with closely coupled turns has a much lower propagation delay than one with the turns spread out in a loose helix.

Do I infer from your comments that you believe that the current continues to flow along the wire at about the speed of light, so that if the wire length stays the same, the propagation delay along the widely spaced helix is the same as for the short one with close spaced turns? That is, that both these cases fall into what you categorize as "other coils", which act the same as the helix in a TWT?

Actually Gene if you look at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

your EZNEC model's current agrees with similar coils in antennas I
measured.

I expect Cecil will ignore what you sent him, or announce it supports
his conclusions by editing the data.

The EZNEC simulation is just one more data point in a large set
of data points that are already widely scattered. EZNEC does not
have magic or God-like properties to override reality especially
when your design results in pages and pages of segmentation
guideline violations. The jury is still out on the question.

You guys have a habit of declaring victory when you score your
first point after trailing 10-0. When only one coil out of a
dozen tests showed the current at each end of the toroidal
coil to be the same, W8JI declared that was proof that all
coils have the same current at each end.

If you will check my postings, you will see that I said
the delay through a coil is what it is and we usually don't
know what it is. But we do know it is NOT instantaneous and
we know it is unlikely to be the 3 nS measured by W8JI.

I was surprised to see EZNEC report the delay as 20% less than
my lower estimate of 10 degrees. But that 8 degrees is 100%
higher than W8JI's measured values.

And there's your pesky posting about standing wave currents.

>> The only "phase" remaining is the cos (kz) term, which is really an amplitude
>> description, not a phase.

If we assume the 1.013 amp at the bottom of the coil occurs when
the forward and reflected currents are in phase, then the 0.7628
amps at the top of the coil would have the currents 82 degrees
out of phase, i.e. a 41 degree phase shift through the coil.
That is, of course, only a rough estimate, but enough different
from the 8 degrees to suspect something is wrong with my suggested
traveling wave antenna.

ok so after reading all this, wich i enjoyed, confused me a bit.

lets say i operate 10-160m and 6m (all band antenna)
, at max 500wout. (typically 200w)

who makes a good commercial choke balun"" w/so239's at the ends??

make/model/where to buy, ??

i've been using a w2du, lots have told me it's not the 'best' money
isn't the issue i'd just like to get a 'good one' ie efficient

thanks

any tips appreciated

I still don't understand how you can continue to assert that there are equal currents at each end of a loading coil when half of your own measurements show a current at the top of the coil that is 73-79% lower than the current at the bottom of the coil.

And I have shown that those currents depend upon where the coil is placed in the standing wave system:

http://www.qsl.net/w5dxp/current.htm
http://www.qsl.net/w5dxp/1WLDIP.GIF

> I expect Cecil will ignore what you sent him, or announce it supports
> his conclusions by editing the data.

Please see my posting answering Gene. The 8 degree delay value is 20% less than my lowest estimate. The 8 degree delay value for the ~70 uH coil is 100% higher than your measured value of 3 nS for a 100 uH coil. The EZNEC value is also suspicious in the face of pages and pages of segmentation violations errors reported by EZNEC.

> Gene Fuller wrote:
>> The only "phase" remaining is the cos (kz) term, which is really
>> an amplitude description, not a phase.

The phase information in a standing wave is in its amplitude and can be used to estimate the difference in phase angles between the forward and reflected currents.

If the current at the top of the coil is 75% of the current at the bottom of the coil, it means that the forward and reflected current phasors are approximately 82 degrees out of phase with each other, i.e. there is roughly a 41 degree phase shift through the coil. That comes from your own measurements.

The latest EZNEC results are just one more data point on a plot already containing many scattered data points.

This is easily proven not to be true by self-resonance testing.
My 75m bugcatcher is self-resonant on my GMC pickup at about
6.6 MHz. If the signal were "propagating axially from one end to
the other close to the speed of light", the self-resonant frequency
would be close to 1 GHz.

Well, folks I finally decided to test my new antennas. First, I decided to shorten the antennas to 4 elements instead of 8 so I could mount the antennas directly on the back of my thinkpad's screen. The 8 el jobs would have made life harder, requiring connectors, mounting plates, etc. All that for just 3db more gain. Nah...

I went on a "war walk" this morning, scanning my neighborhood for any WiFi access points. I've got a neighbor down the street who has one and with my old antennas (2 inverted V's), I could pickup his network from about 5 houses away. With the new antennas, I picked up his system from twice the distance. Nice! As I understand it, a 4 el coaxial colinear
antenna will have about 6dbd gain so getting double the range seems right. I was curious if my setup was directional so I got to the fringe coverage range and turned around 360 degrees but saw no drop in the signals. It seems like microwaves go right through my screen (and me!).

Now to construct a pair of 8 el antennas for my WRT54G router.....

Disclaimer: I am NOT trying to "hack" free internet access from the neighborhood WiFi 802.11b/g systems - that's not what wardriving is about......

3858. The Seven Warning Signs of Bogus Science

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-31 16:02:05 UTC
From: Irv Finkleman <finkirv@shaw.ca>
Message-ID: <442D5289.E6EFBD9A@shaw.ca>
Source record: 62119

I thought this article might be of interest in that we often see claims about certain types of antennas which fall into the category.

From
http://chronicle.com/free/v49/i21/21b02001.htm

POINT OF VIEW
The Seven Warning Signs of Bogus Science
By ROBERT L. PARK

The National Aeronautics and Space Administration is investing close to a million dollars in an obscure Russian scientist's antigravity machine, although it has failed every test and would violate the most fundamental laws of nature. The Patent and Trademark Office recently issued Patent 6,362,718 for a physically impossible motionless electromagnetic generator, which is supposed to snatch free energy from a vacuum. And major power companies have sunk tens of millions of dollars into a scheme to produce energy by putting hydrogen atoms into a state below their ground state, a feat equivalent to mounting an expedition to explore the region south of the South Pole.

There is, alas, no scientific claim so preposterous that a scientist cannot be found to vouch for it. And many such claims end up in a court of law after they have cost some gullible person or corporation a lot of money. How are juries to evaluate them?

Before 1993, court cases that hinged on the validity of scientific claims were usually decided simply by which expert witness the jury found more credible. Expert testimony often consisted of tortured theoretical speculation with little or no supporting evidence. Jurors were bamboozled by technical gibberish they could not hope to follow, delivered by experts whose credentials they could not evaluate.

In 1993, however, with the Supreme Court's landmark decision in Daubert v. Merrell Dow Pharmaceuticals, Inc. the situation began to change. The case involved Bendectin, the only morning-sickness medication ever approved by the Food and Drug Administration. It had been used by millions of women, and more than 30 published studies had found no evidence that it caused birth defects. Yet eight so-called experts were willing to testify, in exchange for a fee from the Daubert family, that Bendectin might indeed cause birth defects.

In ruling that such testimony was not credible because of lack of supporting evidence, the court instructed federal judges to serve as "gatekeepers," screening juries from testimony based on scientific

nonsense. Recognizing that judges are not scientists, the court invited judges to experiment with ways to fulfill their gatekeeper responsibility.

Justice Stephen G. Breyer encouraged trial judges to appoint independent experts to help them. He noted that courts can turn to scientific organizations, like the National Academy of Sciences and the American Association for the Advancement of Science, to identify neutral experts who could preview questionable scientific testimony and advise a judge on whether a jury should be exposed to it. Judges are still concerned about meeting their responsibilities under the Daubert decision, and a group of them asked me how to recognize questionable scientific claims. What are the warning signs?

I have identified seven indicators that a scientific claim lies well outside the bounds of rational scientific discourse. Of course, they are only warning signs -- even a claim with several of the signs could be legitimate.

1. The discoverer pitches the claim directly to the media. The integrity of science rests on the willingness of scientists to expose new ideas and findings to the scrutiny of other scientists. Thus, scientists expect their colleagues to reveal new findings to them initially. An attempt to bypass peer review by taking a new result directly to the media, and thence to the public, suggests that the work is unlikely to stand up to close examination by other scientists.

One notorious example is the claim made in 1989 by two chemists from the University of Utah, B. Stanley Pons and Martin Fleischmann, that they had discovered cold fusion -- a way to produce nuclear fusion without expensive equipment. Scientists did not learn of the claim until they read reports of a news conference. Moreover, the announcement dealt largely with the economic potential of the discovery and was devoid of the sort of details that might have enabled other scientists to judge the strength of the claim or to repeat the experiment. (Ian Wilmut's announcement that he had successfully cloned a sheep was just as public as Pons and Fleischmann's claim, but in the case of cloning, abundant scientific details allowed scientists to judge the work's validity.)

Some scientific claims avoid even the scrutiny of reporters by appearing in paid commercial advertisements. A health-food company marketed a dietary supplement called Vitamin O in full-page newspaper ads. Vitamin O turned out to be ordinary saltwater.

2. The discoverer says that a powerful establishment is trying to suppress his or her work. The idea is that the establishment will presumably stop at nothing to suppress discoveries that might shift the balance of wealth and power in society. Often, the discoverer describes mainstream science as part of a larger conspiracy that includes industry and government. Claims that the oil companies are frustrating the invention of an automobile that runs on water, for instance, are a

sure sign that the idea of such a car is baloney. In the case of cold fusion, Pons and Fleischmann blamed their cold reception on physicists who were protecting their own research in hot fusion.

3. The scientific effect involved is always at the very limit of detection. Alas, there is never a clear photograph of a flying saucer, or the Loch Ness monster. All scientific measurements must contend with some level of background noise or statistical fluctuation. But if the signal-to-noise ratio cannot be improved, even in principle, the effect is probably not real and the work is not science.

Thousands of published papers in para-psychology, for example, claim to report verified instances of telepathy, psychokinesis, or precognition. But those effects show up only in tortured analyses of statistics. The researchers can find no way to boost the signal, which suggests that it isn't really there.

4. Evidence for a discovery is anecdotal. If modern science has learned anything in the past century, it is to distrust anecdotal evidence. Because anecdotes have a very strong emotional impact, they serve to keep superstitious beliefs alive in an age of science. The most important discovery of modern medicine is not vaccines or antibiotics, it is the randomized double-blind test, by means of which we know what works and what doesn't. Contrary to the saying, "data" is not the plural of "anecdote."

5. The discoverer says a belief is credible because it has endured for centuries. There is a persistent myth that hundreds or even thousands of years ago, long before anyone knew that blood circulates throughout the body, or that germs cause disease, our ancestors possessed miraculous remedies that modern science cannot understand. Much of what is termed "alternative medicine" is part of that myth.

Ancient folk wisdom, rediscovered or repackaged, is unlikely to match the output of modern scientific laboratories.

6. The discoverer has worked in isolation. The image of a lone genius who struggles in secrecy in an attic laboratory and ends up making a revolutionary breakthrough is a staple of Hollywood's science-fiction films, but it is hard to find examples in real life. Scientific breakthroughs nowadays are almost always syntheses of the work of many scientists.

7. The discoverer must propose new laws of nature to explain an observation. A new law of nature, invoked to explain some extraordinary result, must not conflict with what is already known. If we must change existing laws of nature or propose new laws to account for an observation, it is almost certainly wrong.

I began this list of warning signs to help federal judges detect scientific nonsense. But as I finished the list, I realized that in our increasingly technological society, spotting voodoo science is a skill that every citizen should develop.

Robert L. Park is a professor of physics at the University of Maryland at College Park and the director of public information for the American Physical Society. He is the author of Voodoo Science: The Road From Foolishness to Fraud (Oxford University Press, 2002).

3859. Amother look at a choke balun.

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-31 16:45:46 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <VsCdnfdyXLhwwbDZRVnygA@bt.com>
Source record: 62120

To choke balun Gurus.

There is, in fact, a transformer in a choke balun which you have ALL forgotten about, or never knew it exists.

It has nothing to do with 1-to-1 or any other turns ratio.

It is a transmission line transformer comprised of the short length of line (coax or just a pair of wires) which passes through the balun. It is the length of line which is wound on the balun to form the choke. (All lengths of line behave as transformers.)

This line has an impedance Zo. If it is coax line then its impedance is usually 50 ohms. If it is a pair of wires laid alongside each other then its impedance depends on wire diameter, wire spacing and permittivity of the insulation. If it is similar to twin speaker cable then it has an impedance of about 130 ohms. The presence of ferrite has hardly any effect.

When the balun is located between the main transmission line and the tuner then on the antenna side of it there can be seen, say, 300, 450 or 600 ohms.

This is transformed to another impedance on the tuner side of the balun.

The transformation depends on line Zo and its length in wavelengths which depends on frequency. On the 160m band very little happens. The frequency is too low and the line is too short. It is only a few turns of wire around the ferrite core.

On the 10 meter band, at the higher frequencies, the winding length on the balun can approach 1/4-wavelength and the 450 ohm main-line impedance can be transformed to something considerably different.

But the tuner couldn't care what it is. Its purpose is to transform whatever it is presented with to 50 ohms. The presence of the balun merely causes a change in tuner L and C settings. Insofar as the tuner and operator are concerned the transformer in the balun does not exist.

When designing a choke balun the number of turns on the choke and the length of wire involved are best restricted to something less than 1/4-wavelength at the highest frequency of use. 1/8-wavelength is suitable.

Restricting turns has the effect of reducing choke inductance and the choking effect at the lowest frequency of use.

But a 2-inch diameter ferrite ring with a modest permeability of 200 or more, wound with 18 awg stranded twin speaker cable, will allow operation from 1.8 to 30 MHz.

With a balun constructed of a number of ferrite slugs over a coaxial cable there is no transformer action at any frequency because the short length of 50-ohm 'transforming' line is terminated at both ends with a 50-ohm line.

Reg, G4FGQ.

"Gene Fuller" <W4SZzzzzzz@att.net> wrote:
> I did not say anything about W8JI's measurements. He had a completely
> different setup, and I had nothing to do with it.

Didn't say you did and it's good that the two were unrelated -
just wanted to point out the contradictions between your
EZNEC results and W8JI's 3 nS measurements.

I have uncovered a slight conceptual error in my traveling wave
antenna simulation. I took care to eliminate reflections between
the top of the coil and the load on the traveling wave wire. But
I didn't do anything to eliminate reflections from the bottom of
the coil. So the current phase at the load at the bottom of the
coil is not from a traveling wave. It is instead from a standing
wave or a combination of the two waves.

The bottom section is one foot long. Knowing the frequency,
e.g. 4 MHz, allows us to calculate the delay in that one foot
of wire, i.e. 0.0041 WL = 1.5 degrees. So the current
phase at the bottom of the coil is -1.5 degrees on 4 MHz.
With the current phase at the top of the coil being 10.72
degrees, that gives a phase shift through the coil of
9.22 degrees which is equivalent to 6.4 nS, more than
double W8JI's measured value still posted to his web page.

It seems to me that, if one wanted to make a choke BalUn that covered a wide frequency range, it could be made with several grades of ferrite in the stack of cores on the coax, a la W2DU, with the highest frequency material at the antenna end.

Digikey sells 3 grades of ferrite made by Steward, in long form beads that are intended for common mode choke applications. The low frequency material is similar to Fair-Rite type 75 (u about 5000). The medium frequency material is similar to type 43 (u about 800). And the high frequency material is similar to type 61, only higher loss (u about 125).

I have long beads in all of these materials, and some more on back order. If someone would volunteer to measure the common mode impedance of each a set of, say, 3 of each type strung on a foot of wire, to find the useful frequency range, I would be happy to lend them the set of cores.

Cec, do you think that knowledge of reflected waves and phase angles
and propagation delays will enable an antenna designer to construct
something that will win contests every time? ;o)

I'd rather place my confidence in screwing an extra length on the top
end of the loaded whip and damn the extra propagation delay.

I nearly didn't post this.

It was no accident. Those numbers are from your model modified
to an 8.5 ft. tall antenna. *Our original agreement was an 8 ft.
tall antenna.* Your antenna was almost 50% longer, and that was a
violation of the agreed upon boundary conditions. If you made
it 50 feet tall the delay through the coil would be even smaller.
I'll send you the modified files.

But, you said "The presence of ferrite has hardly any effect" above. I thought the relative permeability without ferrite was 1. (I am assuming you meant relative permeability since you had no units associated with the number 200.)

> With a balun constructed of a number of ferrite slugs over a coaxial

A choke is supposed to reduce longitudinal currents on the line to
insignificant amounts.

But very often it doesn't. If you have a choke in the line how much
difference does it make if you remove it? If it makes no difference
you might just as well leave it out.

Insertion of a choke does not affect the manner in which the
longitudinal current is induced to flow in the line in the first
place.

The choke may indeed reduce the magnitude of the current at the
location of the choke. But the current always has standing waves and
the choke may merely shift the maximum current of the wave to another
place along the line. The longitudinal current still exists.

Indeed, if a minimum current should exist at the place where the choke
is inserted then the choke may serve no useful purpose and it can be
removed. It could be re-inserted at a place 1/4-wavelength away at a
current maximum where it MIGHT do some good.

All this requires knowledge of where the standing wave resides. But
one never has such knowledge unless one knows the cause. And if one
knows the cause it can be remedied.

The only way to prevent longitudinal currents on feedlines is to
remedy the cause, or to place chokes at every quarterwave interval all
along the line. Shifting the standing wave maximum, however, might be
sufficient to prevent the trouble it may be causing elsewhere in the
system.

The moral is - don't allow large longitudinal currents to be induced
on the feedlines in the first place. It's poor design.

A little bit of the inevitable longitudinal current on the feedline is
harmless.

If it works - don't fix it!

John, I'm afraid you havn't the foggiest idea about how a choke balun works. You are being confused by the Gurus' bafflegab.

A choke balun is a device which permits a balanced circuit to be connected to an unbalanced circuit without interference to the power flow. In this respect it is NOT a transformer. No ratios are involved.

There are two conductors or wires in a transmission line.

In a choke balun the two wires are TOGETHER wound round a ferrite core AS ONE WIRE. It is this pair of wires together, as one wire, which forms the choke using the ferrite core.

The choke has inductance and inductive reactance. The reactance chokes the current which would flow equally in both wires, in the same direction in both wires.

Entirely independently, the pair of wires can carry the normal transmission line currents which flow in oposite directions to each other. If normal currents in the two wires flow in opposite directions to each other then there is no flux induced in the ferrite and the ferrite may just as well not be there.

So the choking action has no effect on normal transmission line operation along the two wires.

The choke only acts on that current which flows along the line when both wires in parallel are considered to be ONE wire.

For longitudinal currents the two wires can be considered as being connected together at both ends. Connected in parallel. It's really a single wire choke.

It's all very simple really. There are two INDEPENDENT currents flowing.

Roy, W7EL wrote:
"I maintain there`s no such group as "other coils", but that coils act quite differently depending on their physical sizes and the amount of coupling between turns."

I wrote:
"That`s how the experts say the coil in a TWT works, and is no different from other coils."

All coils aren`t inside TWTs, but all coils do create inductance.

Bill Orr wrote this concerning the coil in a Traveling Wave Tube:
"Figure 25 is a simplified sketch of a basic helix-type TWT tube. Spaced closely around the beam is a circuit, in this case a helix of tightly wound wire, capable of propagating a slow wave. The r-f energy travels along the wire at the velocity of light, because of the helical path, the energy progresses along the length of the tube at a considerable slower veloity than is determined primarily by the pitch of the helix."

Terman wrote this concerning the coil in a TWT:
"The beam is shot through a long, loosely wound helix, and is collected by an electrode at anode potential as shown."

Lenkurt wrote:
"The RF signal travels as a surface wave around the turns of the helix, toward the collector, at about the velocity of light. The forward or axial velocity is slower, of course, because of the pitch and diameter of the helix."

Orr`s example was a helix of tightly wound wire.

Terman`s example was a long, loosely wound helix, and Lenkurt did not specify how tight or loosely the coil was wound. In all cases the coil retarded the signal well below the velocity of light along the axis that the electron beam traveled so that the beam could keep up with the signal along the path. The beam needs to be speeded as well as slowed for velocity modulation.

Point is that group velocity does not exceed the velocity of light even in W8JI`s coil no matter how he makes it. There is no way to coerce actual energy to exceed the velocity of light. It would turn into a pumpkin or something.

Also, electric current follows the course of maximum potential difference and that`s along the conductor supplying the electrons. The wave impels electrons to move in the conductor.

Kraus wrote:
"The helical antenna, which is discussed in this chapter, may be regarded as the connecting link between the linear antenna and the loop antenna, discussed in preceeding chapters. The helical antenna is the general form of antenna of which the linear and the loop are special cases. Thus, a helix of fixed diameter collapses to a loop as spacing approaches zero. On the other hand, a helix of fixed spacing between turns straightens out into a linear conductor as the diameter approaches zero.

This thread has been about a coil loaded whip. This is a standing wave antenna. When the signal gets to the antenna tip it has no where else to go but return over the path which brought it. The coil has an incident wave impinging from the transmitter and an out-of-phase signal reflected from its tip. These two waves have the same origin so they are locked in step to make standing waves in both voltage and current. These determine the ratios of voltage to current at each point along the signal route. In this respect the coil behaves as a conductor in the antenna. It has more opposition to the signals traversing it than a straight wire but the volts and amps at each of its ends can obviously be very different. Thus, current in one end of the coil can be very different from the current at the other end of the same coil.

Best Regards, Richard Harrison, KB5WZI

From all that, I gather that your answer is "yes", that you do believe
that the current in a small inductor with close turn spacing (i.e., one
where the fields from the turns couple well) flows around and around
along the wire at near the speed of light, resulting in a delay from end
to end approximately equal to the wire length divided by the speed of light.

Or did I misinterpret what you said, and you don't believe this?

There's those buzz words "small inductor" again. We are talking about
75m bugcatcher coils, not "small inductors". Small inductors have a
high self-resonant frequency. We are talking about large inductors
operated relatively near their self-resonant frequencies.

If 100% of the flux from each and every coil physically linked
100% of each and every other coil, the current would indeed skip
from one end of the coil to the other without interference. That
is the basic presupposition of the lumped-circuit model.

Quoting Dr. Corum:
"Lumped element circuit theory assumes that there are no wave
interference phenomena present, ...", i.e. no superposition
of forward and reflected waves, i.e. no standing waves.

Continuing the quote:
"This is manifested by two phenomena: 1. The current distribution
function is spatially uniform across each element. 2. The spatial
phase delay between circuit extremities is zero."

One has to imagine that W8JI's 2" dia x 12" length 100 uH coil
links 100% of the flux in coil number 1 with coil number 100
a foot away and vice versa. That's quite an imagination but W8JI
did measure a 3 nS delay, virtually instantaneous, so it must
be true.

You will, no doubt, chose a piece of Air-Dux so
small that all the flux is linked to every coil.

Instead of a small Air-Dux coil, use a 75m bugcatcher
coil mounted over a ground plane and see what you get.

To nobody in particular.

If the propagation time along a coil is equal to the time taken for the current to travel along the length of wire in the coil at the velocity of light, then, at a given frequency, if a half-wavelength of wire is wound into a coil it should become self-resonant at that frequency.

But it isn't. The coil resonates at a different frequency which depends on the length and diameter of the coil as well as on the length of wire.

Just make a coil, measure its resonant frequency, then measure the length of wire it contains. There will be no direct relationship between resonant frequency and length of wire.

The same experiment can be carried out using pencil and paper.

The resonant frequency will be directly related to wire length only when the coil is stretched out straight. And only then.

Reg.
